- the risk of breast cancer in the oestrogen-alone arm was lower than that in the placebo group. The risk of breast cancer was significantly reduced in women with no previous exposure at study entry; and
- in the combined arm, there was evidence of a duration effect with an increase in risk starting 3 years after randomization, but only in women who had used HRT before entering the study.

The MWS found:

- an increased risk with all HRT regimens (both unopposed oestrogen and combined HRT);
- the greatest degree of risk was with combined HRT and this was not influenced by route of administration; and
- different oestrogens or progestogens did not appear to alter risk, nor did the pattern of progestogen administration (i.e. cyclical or continuous).

The higher risk estimates reported in the MWS compared with the randomized WHI, especially for the oestrogen-alone arm which found a reduced risk, probably reflect the different designs of the studies.

The increased risk of breast cancer with combined HRT compared with oestrogen alone has to be balanced against the reduction in risk of endometrial cancer provided by progestogen addition. The increased risk of breast cancer with long-term use seems to be limited to lean women (BMI <25 kg/m²) in most studies. Also, the increased risk of breast cancer with HRT is low and similar to the risk conferred by obesity, being tall, nulliparity or late age at first full-term pregnancy, and is lower than that conferred by certain inherited genetic mutations or mantle radiotherapy (American Cancer Society 2009).

Also, the risk of breast cancer decreases after stopping HRT, and after 5 years, the risk of breast cancer is no greater than that in women who have never been exposed to HRT. The incidence of breast cancer has been decreasing in the USA and this has been attributed to declining HRT use since publication of the WHI. However, the decrease started in 1998, predating the first WHI publication (Li and Daling 2007).

Endometrial cancer

Unopposed systemic oestrogen replacement therapy increases the risk of endometrial cancer (Weiderpass et al 1999). Sequential progestogen addition, especially when continued for more than 5 years, does not eliminate this risk completely. This has also been found with monthly- and long-cycle HRT. No increased risk of endometrial cancer has been found with continuous combined regimens. Very low doses of systemic oestrogen (0.014 µg/day transdermal

oestradiol patch) do not seem to stimulate the endometrium, but studies are limited and require confirmation (Simon and Snabes 2007).

Furthermore, oral treatment, but not vaginal treatment, with low-potency formulations (such as oestriol) increases the relative risk of endometrial neoplasia. The increased risk of endometrial cancer with systemic oestrogen is lower than that found in obese or diabetic women.

Venous thromboembolism

HRT increases the risk of venous thromboembolism (VTE) two-fold, with the highest risk occurring in the first year of use (Canonica et al 2008). However, the absolute risk is small, being 1.7 per 1000 in women over 50 years of age not taking HRT. Advancing age, obesity and an underlying thrombophilia such as factor V Leiden increase the risk of VTE significantly. Randomized trial data strongly suggest that women who have previously suffered a VTE have an increased risk of recurrence in the first year of HRT use. However, transdermal HRT may be associated with a lower risk, even in women with a thrombophilia.

Gallbladder disease

The WHI confirmed the observation of the Heart and Estrogen/Progestin Replacement Study published in 1998 that oral HRT increases the risk of gallbladder disease. However, the MWS found that transdermal therapy confers a lower risk than oral therapy (Liu et al 2008). Gallbladder disease increases with ageing and with obesity, and HRT users may have silent pre-existing disease.

Uncertainties

CVD (CHD and stroke)

The role of HRT in both primary and secondary prevention remains uncertain.

CHD primary prevention

Until the late 1990s, oestrogen was thought to protect against CHD (Rees and Stevenson 2008). Many cohort studies showed that HRT was associated with a 40–50% reduction in the incidence of CHD. The effects were the same for both oestrogen alone and combined HRT. However, the WHI did not confirm these observational studies. It has become apparent that there are differences between regimens, and that the timing of HRT initiation may be crucial. The WHI found an early, albeit transient, increase in coronary events in the combined arm but not the oestrogen-alone arm. In the WHI oestrogen-alone arm, there was a non-significant reduction in CHD, which was most marked in younger women (50–59 years). With regard to timing, women in the WHI who started combined HRT within 10 years of the menopause had a lower risk of CHD than women who started later (Rossouw et al 2007). Combining the two HRT arms found that women who initiated hormone therapy closer to the menopause tended to have reduced CHD risk compared with the increase in CHD risk among women who initiated hormone therapy more distant from the menopause. While transdermal oestrogen has less of an effect on coagulation than oral therapy due to avoidance of the first liver pass, it is uncertain whether transdermal delivery is better than oral delivery in terms of CHD risk.

CHD secondary prevention

Although angiographic and cohort studies such as the Nurses' Health Study suggested a role of oestrogen in the secondary prevention of CHD, this has not been confirmed in randomized-controlled trials with both oral and transdermal therapy (Grodstein et al 2006).

Stroke

Interpretation of observational studies on HRT and stroke is difficult because of differences in design and failure to distinguish between ischaemic and haemorrhagic stroke (Billeci et al 2008). Both arms of the WHI found an increase in ischaemic stroke but not haemorrhagic stroke. However, age or time since menopause did not affect the risk of stroke. In addition, in women who have experienced a previous ischaemic stroke, oestrogen replacement does not reduce mortality or recurrence as evidenced by randomized-controlled trials.

Dementia and cognition

While oestrogen may delay or reduce the risk of Alzheimer's disease, it does not seem to improve established disease (Barber et al 2005). It is unclear if there is a critical age or duration of treatment for exposure to oestrogen to have an effect on prevention, but there may be a window of opportunity in the early postmenopause when the pathological processes that lead to Alzheimer's disease are starting and when HRT may have a preventive effect. The WHI found an increased risk of dementia and lower cognitive function in HRT users, but only in women aged over 75 and 65 years, respectively.

Ovarian cancer

Most data pertain to replacement with oestrogen alone with increasing risk in the very long term (>10 years) (Beral et al 2007). However, with continuous combined therapy, this increase does not seem apparent.

Quality of life

While some studies have shown improvement in both symptomatic and asymptomatic women, others have not. This area is difficult to evaluate because of the different questionnaires used, as well as varying levels of menopausal symptomatology.

Tibolone

Tibolone is effective in the treatment of menopausal symptoms. It conserves bone mass and reduces the risk of vertebral and non-vertebral fractures, particularly in patients who have already had a vertebral fracture. It also reduces the risk of invasive breast cancer and colon cancer. However, it does not significantly reduce the risk of hip fracture and it increases the risk of stroke (Cummings et al 2008). The LIFT study also showed that tibolone does not have a deleterious effect on CHD or VTE (Cummings et al 2008). The MWS showed an increased risk of breast cancer and endometrial cancer. However, the increased risk of endometrial cancer has not been confirmed in randomized-controlled trials (Archer et al 2007). The LIBERATE randomized trial of tibolone in breast cancer survivors was discontinued early in

2007 as there was an excess of breast cancer recurrences in the group of women randomized to receive tibolone (Kemmans et al 2009).

Non-Oestrogen-Based Treatments for Menopausal Symptoms

Non-oestrogen-based treatments are used to treat hot flushes and symptoms of urogenital atrophy. These can be either hormonal or non-hormonal (Writing Group for the British Menopause Society Council 2008).

Hormonal

Progestogens

Progestogens such as 5 mg/day norethisterone or 40 mg/day megestrol acetate can reduce hot flushes and night sweats. However, the risk of VTE may be increased with the doses of progestogen used. Also, safety with regard to the breast is uncertain. Availability of megestrol acetate 40 mg tablets varies worldwide.

Non-hormonal

Clonidine

Clonidine is a centrally acting α -adrenoceptor agonist that was originally developed for the treatment of hypertension. While it may be of limited help in women with tamoxifen-induced hot flushes, the evidence for efficacy is conflicting. Side-effects include dry mouth, sedation, dizziness, nausea and nocturnal restlessness. The dose is 50–75 μ g twice daily.

Selective serotonin reuptake inhibitors and serotonin and noradrenaline reuptake inhibitors

Fluoxetine, paroxetine, citalopram and venlafaxine have been found to be effective in several studies. However, most are short lasting (only a few weeks). The most convincing data are for venlafaxine [selective serotonin and noradrenaline reuptake inhibitor (SNRI)] at a dose of 37.5 mg twice daily. A randomized trial of a new SNRI, desvenlafaxine, has shown a 64% reduction in hot flushes at 12 weeks. Side-effects include gastrointestinal symptoms (nausea) and sexual dysfunction (delayed or absent orgasm). Some early evidence suggests that selective serotonin reuptake inhibitors may cause bone loss.

Gabapentin

Gabapentin is a γ -aminobutyric acid analogue used to treat epilepsy, neurogenic pain and migraine. It reduces hot flushes at a dose of 900 mg/day by approximately 50%. Side-effects include dry mouth, dizziness and drowsiness, which may improve with continued use.

Vitamin E

Although one study showed that vitamin E reduced hot flushes, the difference between the active and placebo groups was not significant.

Vaginal lubricants and moisturizers

Lubricants usually consist of a combination of protectants and thickening agents in a water-soluble base. They are usually used to relieve vaginal dryness during intercourse. They therefore do not provide a long-term solution. Lubricants must be applied frequently for more continuous relief, and require reapplication before intercourse. Moisturizers may contain a bioadhesive polycarbophil-based polymer, which attaches to mucin and epithelial cells on the vaginal wall and retains water. Moisturizers are promoted as providing long-term relief of vaginal dryness and need to be applied less frequently. Petroleum-based products and baby oil can compromise the integrity of condoms. This is important when condoms are used for contraception and/or to prevent sexually transmitted infections.

Non-Oestrogen-Based Therapy for Osteoporosis

A wide range of pharmacological and non-pharmacological interventions are available (Table 28.4) (Writing Group on Osteoporosis for the British Menopause Society Council 2007). There are very few data regarding long-term efficacy for reducing fractures (i.e. more than 10 years of treatment) and safety of combinations of therapy. Most of these therapies have been studied in elderly women (>60 years) who

have osteoporosis or who are at increased risk of the disease. Little is known about their efficacy and safety in women with premature menopause and effects on the developing fetal skeleton. This is of importance because of the long (many years) half-life of bisphosphonates and strontium ranelate.

Pharmacological interventions

All pharmacological interventions except for parathyroid hormone and strontium ranelate act mainly by inhibiting bone resorption.

Bisphosphonates

Bisphosphonates are chemical analogues of naturally occurring pyrophosphates and are classified into two groups: non-nitrogen-containing bisphosphonates, such as etidronate; and nitrogen-containing bisphosphonates, such as alendronate, risedronate, ibandronate and zoledronic acid.

All bisphosphonates are absorbed poorly from the gastrointestinal tract and must be given on an empty stomach. Food or calcium-containing drinks inhibit absorption, which at best is only 5–10% of the administered dose. The principal side-effect of all bisphosphonates is irritation of the upper gastrointestinal tract. Symptoms resolve quickly after drug withdrawal and are reduced by using weekly or monthly dosing rather than daily dosing.

Alendronate, risedronate, etidronate and ibandronate are used in the prevention and treatment of osteoporosis. The indication for zoledronic acid is the treatment of osteoporosis in postmenopausal women at increased risk of fracture. Alendronate, risedronate and etidronate are also used in corticosteroid-induced osteoporosis.

The question of how long to prescribe a bisphosphonate has not been fully clarified because of concerns about 'frozen bone', with complete turning off of bone remodelling with long-term use and also development of osteonecrosis in the jaw. Of note, most reports about osteonecrosis refer to high-dose intravenous bisphosphonates used in the oncological setting rather than oral bisphosphonates for osteoporosis. There have been concerns regarding atrial fibrillation with bisphosphonates, but mainly with intravenous regimes, and the mechanism is uncertain.

Five years of treatment with a 2-year 'holiday' have been proposed for alendronate, but differences may exist with individual bisphosphonates. This may not be applicable to glucocorticoid-induced osteoporosis.

Alendronate reduces vertebral and non-vertebral fractures by 50% in randomized-controlled trials. The dose for prevention of osteoporosis is 5 mg/day or 35 mg once weekly, and the dose for treatment of established disease is 10 mg/day or 70 mg once weekly.

Risedronate reduces vertebral and non-vertebral fractures in randomized-controlled trials. The dose for treatment of established disease is 5 mg/day or 35 mg once weekly.

Ibandronate reduces vertebral but not non-vertebral fractures by 50% in randomized-controlled trials undertaken in postmenopausal women. The dose is 2.5 mg/day or 150 mg once monthly orally or 3 mg intravenously every 3 months.

Etidronate reduces the risk of vertebral but not non-vertebral fractures. It is given intermittently (400 mg on 14

Table 28.4 Interventions for the prevention and treatment of osteoporosis

	Spine	Hip
1. Bisphosphonates		
Etidronate	A	B
Alendronate	A	A
Risedronate	A	A
Ibandronate	A	ND
Zoledronic acid	A	A
2. Calcium and vitamin D	ND	A
3. Calcium	A	B
4. Calcitriol	A	ND
5. Calcitonin	A	B
6. Oestrogen	A	A
7. Raloxifene	A	ND
8. Strontium ranelate	A	A
9. Parathyroid hormone peptides	A	ND
ND, not demonstrated. The levels of evidence for the various agents are: A = meta-analysis of randomized-controlled trials (RCTs) or from at least one RCT/ from at least one well-designed controlled study without randomization; B = from at least one other type of well-designed quasi-experimental study or from well-designed non-experimental descriptive studies, e.g. comparative studies, correlation studies, case-control studies.		

out of every 90 days) with 1250 mg calcium carbonate (which, when dissolved in water, provides 500 mg calcium as calcium citrate) during the remaining 76 days.

Zoledronic acid significantly reduces the risk of vertebral, hip and other fractures. It is administered intravenously (5 mg annually) and has been evaluated in the treatment of postmenopausal osteoporosis.

Strontium ranelate

Strontium is an alkaline earth element like calcium and is thus incorporated into the skeleton. It reduces the risk of vertebral and hip fractures. The dose is a 2 g sachet/day. It can cause diarrhoea but this resolves on stopping treatment. There appears to be a small increased risk (<1%) of VTE and nervous system disorders (headaches, seizures, memory loss and disturbance in consciousness), but data are limited. Strontium ranelate causes a clinically significant overestimation of BMD because of the high attenuation of X-rays by strontium atoms in bone as it has a higher atomic number than calcium.

Raloxifene

Raloxifene is a selective oestrogen receptor modulator (SERM). These compounds possess oestrogenic actions in certain tissues and antioestrogenic actions in others (Palacios 2007). Other SERMs such as bazedoxifene, arzoxifene, lasofoxifene and ospemifene are currently being evaluated.

Raloxifene reduces vertebral, but not non-vertebral, fractures by 30–50%, depending on the dose. The dose is 60 mg/day. It also reduces the risk of breast cancer to the same extent as tamoxifen. Side-effects include hot flushes and calf cramps. It was thought that it could be cardioprotective from its effects on surrogate markers such as lipids; however, the Raloxifene Use for the Heart study found that it did not reduce the risk of CHD and it increased the risk of fatal stroke and VTE.

Parathyroid hormone peptides

Recombinant 1–34 parathyroid hormone, given as a subcutaneous daily injection of 20 µg, reduces vertebral and non-vertebral fractures in postmenopausal women with osteoporosis. The full 1–84 parathyroid hormone peptide is given in the same way in a daily dose of 100 µg. They both reduce the risk of vertebral fractures but not hip fractures.

Calcitonin

Calcitonin can be given by subcutaneous or intramuscular injection or by nasal spray. An oral preparation is in development. Nasal calcitonin has also been shown to reduce new vertebral fractures in women with established osteoporosis. It may help with pain in the context of an acute vertebral fracture. It may also be helpful as adjunctive treatment after surgery for hip fracture.

Calcitriol

This is the active metabolite of vitamin D and facilitates the intestinal absorption of calcium. The potential dangers of hypercalcaemia and hypercalciuria mean that levels

of calcium in serum and urine should be monitored closely. Studies of the effects of calcitriol on bone loss and fractures have produced conflicting results. As such, its use is limited.

Future developments

New treatments are focusing on inhibition of bone turnover (McClung 2007). Receptor activator of nuclear factor-κB ligand (RANKL) is a pivotal regulator of osteoclast activity that provides a new therapeutic target. Denosumab, a highly specific anti-RANKL antibody, reduces bone resorption. Pharmacokinetics of the antibody allow dosing by subcutaneous injection every 3 or 6 months.

Non-pharmacological interventions

Calcium and vitamin D

Provision of adequate dietary or supplemental calcium and vitamin D is an essential part of osteoporosis management, and is the placebo component of clinical trials of agents such as bisphosphonates. Most studies show that approximately 1.5 g elemental calcium is necessary to preserve bone health in women who are not taking HRT. However, the effects of calcium and vitamin D supplements, alone or in combination, on fracture are contradictory and may depend on the study population and compliance with therapy (Tang et al 2007, Lin and Lane 2008). For example, people in sheltered accommodation or residential care may be more frail, have lower dietary intakes of calcium and vitamin D, and are at higher risk of fracture than those living in the community.

Caution has been expressed about the use of supplements in women whose diet is already adequate. Increased risk of kidney stones and CVD has been reported.

Hip protectors

Hip protectors are used to reduce the impact of falling directly on the hip, but evidence of efficacy is conflicting in both community and institutional studies. A systematic review found no evidence of the effectiveness of hip protectors from studies in which randomization was by individual patient within an institution or those living in their own homes (Parker et al 2006).

Diet and exercise

Maintaining a good diet and regular exercise are essential for healthy ageing and reducing the risk of CVD, osteoporosis, urinary incontinence and dementia (Salerno-Kennedy and Rees 2007).

Dietary components

Diet consists of macronutrients and micronutrients. Macronutrients encompass carbohydrate, protein and fat. The World Health Organization recommends that 55–75% of energy input should come from carbohydrate, with less than 10% from free sugars. Emphasis should be placed on carbohydrate-rich foods (e.g. wholegrain breakfast cereals, grains, and breads and bakery products), which also provide fibre and a number of B vitamins.

Protein is an important nutrient for older women and should comprise 10–15% of total energy intake. Total fat intake should account for 15–30% of total energy intake, with saturated fats accounting for less than 10% and polyunsaturated fats for 6–10%. Although, in the past, the main message has been to limit the total amount of fat, particular types such as omega-3 fatty acids, found mainly in oily fish, are important to health.

Micronutrients include vitamins and minerals. Those that may be associated with deficiencies in postmenopausal women include vitamin B12, vitamin A, vitamin C, vitamin D, calcium and other trace minerals. Low intakes of iron, folate and vitamin B12 can cause anaemia as well as other problems such as neuropathies and dementia.

It has been suggested that antioxidant supplements may reduce mortality. However, a systematic review found that vitamin A, beta-carotene, and vitamin E supplements may increase mortality (Bjelakovic et al 2008). No detrimental effects were found with vitamin C or selenium. Of note, most trials in the systematic review investigated the effects of supplements administered at higher doses than those commonly found in a balanced diet, and some of the trials used doses above the recommended daily allowances. These trials should not deter women from consuming fruit and vegetables which contain other substances such as fibre and flavonoids.

Functional foods

A functional food may be defined as a food with health-promoting benefits and/or disease-preventing properties over and above its usual nutritional value (Rudkovska 2008). Functional foods are also known as 'nutraceuticals' or 'designer foods'. They encompass a broad range of products, ranging from foods generated around a particular functional ingredient (e.g. stanol-enriched margarines), through to staple everyday foods fortified with a nutrient that would not normally be present to any great extent (e.g. bread or breakfast cereals fortified with folic acid). Functional foods that show promise in postmenopausal health include probiotics, prebiotics, phytosterols and stanols, omega-3 fatty acids, flavonoids and fibre.

Isoflavones can also be considered as a functional food and are discussed in the section on complementary and alternative therapies. Synbiotics are a food or supplement product containing both probiotics and prebiotics. The name derives from a proposed synergism between probiotics and prebiotics.

Probiotics are live micro-organisms that, when administered in adequate amounts, confer a health benefit on the host. Currently, the best studied probiotics are different species of *Lactobacillus* or *Bifidobacterium*, and the yeast *Saccharomyces cerevisiae* (*boulardii*). These can be combined in cereals, food bars, yoghurts and drinks. Various health benefits have been proposed. These include: regulation of immune function, prolongation of inflammatory bowel conditions, shortening the duration of infectious diarrhoea in infants, enhanced gastrointestinal tolerance to antibiotic therapy, and control of symptoms associated with lactose intolerance. They may also improve therapeutic outcome for women being treated for bacterial vaginosis, and reduce the severity of symptoms or the incidence of respiratory infections.

Prebiotics are non-digestible food ingredients such as inulin that beneficially affect the host by selectively stimulating the growth and/or activity of one or a limited number of bacteria in the colon. Thus, prebiotics are food for bacterial species that are considered beneficial for health and well-being.

Phytosterols and stanols reduce low-density-lipoprotein cholesterol by 10% and thus have the potential to reduce the risk of CHD by approximately 25%. Plant sterols and stanols reduce the absorption of cholesterol from the gut, and therefore reduce serum concentrations of cholesterol. They are incorporated into a variety of foods such as spreads, yogurts and drinks. However, studies with the endpoints of cardiovascular events are awaited.

Omega-3 fatty acids include the plant-derived α -linolenic acid (18:3n-3), and the fish-oil-derived eicosapentaenoic acid (20:5n-3) and docosahexaenoic acid (22:6n-3). Consumers of oily fish have a lower risk of CVD. Consumption of a diet rich in omega-3 fatty acids may also protect against dementia and Alzheimer's disease.

Flavonoids are a large family of polyphenolic compounds synthesized by plants. They are found in a wide variety of fruit and vegetables such as grapes, berries, apples, chocolate, teas, kale and hot peppers. Isoflavones are a subclass of flavonoids with oestrogenic activity. Epidemiological evidence suggests that flavonoids reduce the risk of CVD. This would explain the inverse relationship between the consumption of red wine and CVD mortality (the 'French paradox'). Animal and in-vitro studies suggest that flavonoids may have a role in preventing cancer and neurodegenerative disease.

Dietary fibre consists of plant substances that resist hydrolysis by digestive enzymes in the small bowel, and is an extremely complex group of substances. Fibre can be classified according to its solubility and fermentability by bacteria: a soluble fibre is readily fermentable by colonic bacteria, and an insoluble fibre is only slowly fermentable. Fibres may act in several ways, including through gel-forming effects in the stomach and small intestine, fermentation by colonic bacteria, a 'mop and sponge' effect and concomitant changes in other aspects of the diet. These actions lead to potentially beneficial effects in the gastrointestinal tract and systemically, such as lowering serum cholesterol and improving glycaemic control.

The importance of diet is such that the American Heart Association recommends that 'Women should consume a diet rich in fruits and vegetables; choose wholegrain, high-fibre foods; consume fish, especially oily fish, at least twice a week; limit intake of saturated fat to <10% of energy, and if possible to <7%, cholesterol to <300 mg/day, alcohol intake to no more than 1 drink per day, and sodium intake to <2.3 g/day (approximately 1 tsp salt). Consumption of trans-fatty acids should be as low as possible (e.g. <1% of energy)' (Mosca et al 2007).

Exercise

Regular physical activity reduces the risk of CHD, osteoporotic fractures and type 2 diabetes mellitus. Hot flushes, urinary incontinence, insomnia and depression may also be helped. A systematic review found that no conclusions regarding the effectiveness of exercise as a treatment for

vasomotor menopausal symptoms could be made due to a lack of trials (Daley et al 2007). With regard to CVD, the Nurses Health Study found that low intensity exercise, such as walking, conferred the same benefit as vigorous exercise, and sedentary women who became active late in life reaped similar benefits as those who remained active throughout their life (Manson et al 2002). Exercise has a key role in the prevention and treatment of osteoporosis. A Cochrane review found that fast walking improved bone density effectively in the spine and the hip, whereas weight-bearing exercises were associated with increases in bone density of the spine but not the hip (Bonaiuti et al 2003).

Exercise regimens can be very helpful in the management of established osteoporosis, and represent a component of falls prevention programmes. Pelvic floor exercises are used commonly for stress incontinence. They are also used in the treatment of women with mixed incontinence, and less commonly for urge incontinence. Systematic reviews support the view that pelvic floor muscle training and bladder training should be included in first-line conservative management programmes for women with stress, urge or mixed urinary incontinence (Shamliyan et al 2008).

Complementary and alternative medicine

Many women use complementary and alternative medicine in the belief that they are safer and 'more natural', especially with concerns regarding the safety of oestrogen-based HRT after publication of the WHI and the MWS. However, evidence from randomized trials for complementary and alternative medicine that improves menopausal symptoms or has the same benefits as HRT is poor (Nedrow et al 2006). Very little well-designed research has been undertaken. The range of approaches used includes botanicals, homeopathy, DHEA, transdermal progesterone creams and mechanical methods (e.g. acupuncture, magnetism).

Botanicals

The evidence from clinical trials on the benefit of botanicals on menopausal symptoms is limited and conflicting. Studies may use different products which are not chemically consistent, making comparison difficult. Also, the stability of individual chemicals may vary and may depend on the type of packaging. Herbs may contain many chemical compounds, the individual and combined effects of which are unknown.

A major concern is use without consulting a health professional, leading to interaction with standard pharmacopeia with potentially fatal consequences. Severe adverse reactions, including renal and liver failure and cancer, have been reported. Concern exists regarding the quality control of production. Some have been found to be contaminated or to contain unlabelled ingredients such as conventional medicines (steroids) or banned substances. While a European Union Directive on traditional herbal medicinal products was implemented in October 2005 in the UK, this will not cover preparations bought by women outside Europe.

Herbal remedies need to be used with caution in women with a contraindication to oestrogen, as some botanicals

have oestrogenic properties (e.g. soy, red clover, ginseng). Thus, they should not be used by women with a hormone-dependent condition such as breast cancer or endometriosis. They may interact with selective oestrogen receptor modulators (e.g. tamoxifen, raloxifene) or aromatase inhibitors (e.g. anastrozole, letrozole). Other consequences of herb-drug interactions include bleeding when combined with warfarin or aspirin; hypertension, coma and mild serotonin syndrome when combined with serotonin reuptake inhibitors; and reduced efficacy of antiepileptics and oral contraceptives.

Phytoestrogens are plant substances that have effects similar to those of oestrogens. Preparations vary from enriched foods, such as bread or drinks (e.g. soy milk), to tablets containing plant extracts. The most important groups are the isoflavones and lignans. The major isoflavones are genistein and daidzein. The major lignans are enterolactone and enterodiol. The role of phytoestrogens has stimulated considerable interest, as people from populations that consume a diet high in isoflavones, such as the Japanese, seem to have lower rates of menopausal vasomotor symptoms; CVD; osteoporosis; and breast, colon, endometrial and ovarian cancers. PHYTOS, ISOHEART and PHYTOPREVENT are European Union studies examining the role of phytoestrogens in osteoporosis, heart disease and cancer. With regard to menopausal symptoms, the evidence from randomized placebo-controlled trials in Western populations is conflicting for soy and derivatives of red clover (Lethaby et al 2007). Similarly, debate also surrounds the effects on lipoproteins, endothelial function, blood pressure, cognition and the endometrium. Endometrial hyperplasia has been reported in soy users. Further well-designed randomized trials are needed to determine the role and safety of phytoestrogen supplements in perimenopausal and postmenopausal women and those who have survived cancer.

Actaea racemosa (black cohosh) is a herbaceous perennial plant native to North America, used widely to alleviate menopausal symptoms. The results from placebo-controlled trials are conflicting. There is no consensus regarding whether non-oestrogenic or oestrogenic actions are involved in the mechanisms by which it relieves hot flushes. Little is known regarding long-term safety, and liver toxicity has been reported.

Evening primrose oil is rich in γ -linolenic acid. One small placebo-controlled, randomized trial showed it to be ineffective for the treatment of hot flushes.

Angelica sinensis (dong quai) is a perennial plant native to south-west China. It was not found to be superior to placebo in a randomized trial, but may be effective when combined with other herbs. Interaction with warfarin and photosensitization have been reported.

Ginkgo biloba (gingko) is widely used but there is little evidence that it improves menopausal symptoms.

Panax ginseng (ginseng) is a perennial herb native to Korea and China. It does not appear to be effective for hot flushes. Case reports have associated ginseng with postmenopausal bleeding and mastalgia. Interactions have been observed with warfarin, phenelzine and alcohol.

Piper methysticum (kava kava) may be an effective symptomatic treatment for anxiety, but the data about menopausal

symptoms are conflicting. Concern about liver damage has led regulatory authorities to suspend or withdraw kava kava.

Wild yam cream, dong quai, St John's wort, *Agnus castus* (Chasteberry), liquorice root and Valerian root are also popular, but no good evidence shows that they have any effect on menopausal symptoms. Claims have been made that steroids (e.g. diosgenin) in yams (*Dioscorea villosa*) can be converted to progesterone in the body, but this is biochemically impossible in humans.

Homeopathy

Samuel Hahnemann (1755–1843), a German physician and scientist, was the first to enunciate the central tenets of homeopathic philosophy. He believed in a 'vital force' that animates and regulates the human form and directs growth, healing and repair. He postulated that a homeopathic remedy acted through the vital force. He then put forward the principle of 'similars', which claims that patients with particular signs and symptoms can be cured if given a drug that produces the same signs and symptoms in a healthy individual. He then pursued the concepts of minimum dose and succession (the curative action of certain preparations seemed to be stronger at some of the lower doses, particularly when shaken vigorously). The underlying mechanisms of homeopathy are scientifically unclear. While limited data are encouraging, further research is needed.

Dehydroepiandrosterone

DHEA is a steroid secreted by the adrenal cortex. Blood levels of DHEA decrease dramatically with age. This led to suggestions that the effects of ageing can be counteracted by DHEA 'replacement therapy'. In the USA, it is classed as a food supplement. No evidence shows that DHEA has any effect on hot flushes (Raven and Hinson 2007). Some studies have shown benefits on the skeleton, cognition, well-being, libido and vagina. The safety of long-term use is, as yet, unknown.

Progesterone transdermal creams

Progesterone is available in gels and creams. One licensed gel is available in Europe; however, it is indicated for local use on the breast but not for systemic therapy. A vaginal gel for endometrial protection has been studied. Progesterone creams have been advocated for the treatment of menopausal symptoms and skeletal protection. However, at present, insufficient published data show that transdermal progesterone has a positive effect on vasomotor symptoms or the skeleton. There is also no consistent evidence that transdermal progesterone creams can prevent mitotic activity or induce secretory change in an oestrogen-primed endometrium. Thus, it should not be used for endometrial protection in women using systemic oestrogen.

Mechanical

These approaches include acupuncture, reflexology, magnetism acupressure, Alexander technique, Ayurveda, osteopathy

and Reiki. Data with regard to the menopause are scant, and well-designed adequately powered studies are required.

Premature Ovarian Failure

POF is responsible for 4–18% of cases of secondary amenorrhoea and 10–28% of cases of primary amenorrhoea. It is estimated to affect 1% of women under 40 years of age and 0.1% of those under 30 years of age. Although the terms 'POF' and 'premature menopause' are often used interchangeably, there is debate regarding which term is best. Some women with POF will have oligomenorrhoea, and have persisting sporadic ovarian activity and can become spontaneously pregnant (Nelson et al 2005). In contrast, menopause implies permanent cessation of ovarian activity and menstruation, and infertility. With regard to an age cut-off, premature menopause should ideally be defined as menopause that occurs at an age more than two standard deviations below the mean estimated for the reference population. In the absence of reliable estimates of age of natural menopause in developing countries, the age of 40 years is often used as an arbitrary limit below which the menopause is said to be premature. In the developed world, however, an age of 45 years should be taken as the cut-off point.

Aetiology

Primary premature ovarian failure

Primary POF can occur at any age, even in teenagers. It can present as primary or secondary amenorrhoea or oligomenorrhoea. In the great majority of cases, no cause is found. Traditionally, ovarian failure has been associated with one of two scenarios:

- a deficient number of primordial follicles from the onset of menarche or accelerated follicle atresia; or
- follicles resistant to stimulation by gonadotrophins.

In the absence of a non-invasive test to differentiate between follicular depletion or dysfunction, the only alternative is ovarian biopsy. The validity of single biopsies has been questioned, with pregnancies occurring despite histological lack of follicles in the biopsy material.

The causes are detailed in Box 28.2.

Box 28.2 Causes of premature ovarian failure

Primary

Chromosome abnormalities
FSH receptor gene polymorphism and inhibin B mutation
Enzyme deficiencies
Autoimmune disease

Secondary

Chemotherapy and radiotherapy
Bilateral oophorectomy or surgical menopause
Hysterectomy without oophorectomy
Infection

Chromosome abnormalities

Two intact X chromosomes are required for normal follicular development. A critical region on the X-chromosome (*POF1*), which ranges from Xq13 to Xq26, which relates to normal ovarian function has been identified, as has a second gene of paternal origin (*POF2*), which is located at Xq13.3–q21.1. Idiopathic POF can be familial or sporadic, and the familial pattern of inheritance is compatible with X-linked with incomplete penetrance or an autosomal-dominant mode of inheritance. Complete absence of one X chromosome (45XO) in Turner's syndrome results in ovarian dysgenesis and primary ovarian failure. Familial POF has been linked with fragile X permutations. Women with Down's syndrome (Trisomy 21) also have an early menopause. Blepharophimosis/ptosis/epicanthus (BEPS) syndrome is a rare autosomal-dominant condition that leads to congenital abnormalities of the eye. In BEPS I, eyelid malformation cosegregates with POF and has been mapped to chromosome 3q.17.

FSH receptor gene polymorphism and inhibin B mutation

Gonadotrophin resistance can lead to the clinical features of POF, and this has been shown in a cohort of Finnish families. This is a very rare cause. In addition, a mutation in the inhibin gene has been identified. These patients experienced ovarian failure at an early age, often before the second decade of life.

Enzyme deficiencies

A number of enzyme deficiencies have been found to be associated with an increased risk of POF. The most common is galactosaemia. Other enzyme abnormalities associated with POF include deficiencies of 17 α -hydroxylase, 17–20 desmolase and cholesterol desmolase.

Autoimmune disease

POF is frequently associated with autoimmune disorders, particularly hypothyroidism (25%), Addison's disease (3%) and diabetes mellitus (2.5%). Other coexisting conditions may include Crohn's disease, vitiligo, pernicious anaemia, systemic lupus erythematosus and rheumatoid arthritis.

Secondary premature ovarian failure

Secondary POF is becoming more important as survival after the treatment of malignancy continues to improve. Techniques to conserve ovarian tissue or oocytes before cancer therapy should help with maintenance of fertility. The causes of secondary POF are detailed below.

Chemotherapy and radiotherapy

The likelihood of ovarian failure after chemotherapy or radiotherapy depends on the agent used, dosage levels, interval between treatments and, particularly, the age of the patient, which probably reflects the age-related progressive natural decline in the oocyte pool. The prepubertal ovary is relatively resistant to the effects of chemotherapeutic alkylating agents. The use of GnRH analogues to suppress ovarian activity in order to mimic prepubertal protection is, as yet, not supported by randomized-controlled trials.

Bilateral oophorectomy or surgical menopause

This results in an immediate menopause which may be intensely symptomatic. The implications of this procedure require detailed discussion with the patient in view of the increased morbidity and mortality in those who cannot, or will not, take oestrogen replacement. This area is of increasing importance in those having prophylactic oophorectomy such as BRCA1 gene carriers.

Hysterectomy without oophorectomy/uterine artery embolization

Both procedures can diminish ovarian reserve and lead to ovarian failure. Diagnosis may be difficult in women where the procedures have made them amenorrhoeic.

Infection

Tuberculosis and mumps are infections that have been implicated most commonly. Malaria, varicella and shigella infections may also cause POF.

Consequences of premature ovarian failure

Women with untreated premature menopause are at increased risk of developing osteoporosis, CVD, cognitive decline, dementia and Parkinsonism, but at lower risk of breast malignancy (Shuster et al 2008). Mean life expectancy in women with menopause before the age of 40 years is 2 years shorter than that in women with menopause after the age of 55 years.

Management

Patients must be provided with adequate information about the condition, its implications on long-term health, use of oestrogen replacement and fertility (Pitkin et al 2007). In those who have not had an oophorectomy, the return of spontaneous ovarian activity and the possibility of spontaneous pregnancy must be explained. While pregnancy may be welcomed by some, this is not true for all women. Women who do not wish to have children need to consider using an effective form of contraception.

Hormone replacement therapy

Oestrogen replacement therapy is the mainstay of treatment for women with POF and is recommended until the average age of natural menopause. This view is endorsed by regulatory bodies. This does not increase the risk of breast cancer to a level greater than that found in normally menstruating women, and women with POF do not need to start mammographic screening early (Ewertz et al 2005). HRT or the combined contraceptive pill may be used. The choice of which to use largely depends on the patient's age, with the former being more likely to be acceptable to women in their 30s and 40s and the latter being more likely to be acceptable to women in their 20s. There is no evidence to support the efficacy or safety of the use of non-oestrogen-based treatments, such as bisphosphonates, strontium ranelate or raloxifene, in these women. Some patients report reduced libido or sexual function despite apparently adequate doses of oestrogen replacement.

ment, especially oophorectomized women, and they may need testosterone addition.

Fertility and contraception

It is important to ascertain whether or not the woman wishes to have children. While women with premature menopause have traditionally been considered to be infertile, the lifetime chance of spontaneous conception in women with karyotypically normal POF has been estimated at 5–15%. A number of ovarian reserve tests (ORTs) have been designed to determine oocyte reserve and quality (Broekmans et al 2006). These include early-follicular-phase blood values of FSH, oestradiol, inhibin B and anti-Müllerian hormone, antral follicle count, ovarian volume, ovarian blood flow, the clomiphene citrate challenge test, the exogenous FSH

ORT and the gonadotrophin agonist stimulation test. A systematic review of ORTs has shown that they only have modest-to-poor predictive properties.

Donor oocyte in-vitro fertilization (IVF) is the treatment of choice for women with primary and secondary POF (Lee et al 2006). In women having chemotherapy or radiotherapy, IVF with embryo freezing prior to treatment currently offers the highest likelihood of a future pregnancy should they experience POF as a result of their treatment. Recent advances in oocyte preservation have improved livebirth rates following freezing of mature eggs. It is still less successful than embryo freezing. Ovulation induction risks delaying treatment. Cryopreservation of ovarian tissue is still largely experimental, although pregnancies have been reported. This technique would be an option for prepubertal girls in whom ovulation induction is not possible.

KEY POINTS

1. The menopause is the permanent cessation of menstruation resulting from loss of ovarian follicular activity, and occurs in the early 50s. Worldwide, the elderly population is increasing, with women forming the majority. Thus, chronic diseases affecting postreproductive health spanning over several decades are major public health issues. The major issues affecting postmenopausal women are vasomotor symptoms, psychological disorders, urogenital atrophy, sexual dysfunction, osteoporosis, CVD, dementia and urinary incontinence.
2. HRT relieves menopausal symptoms and conserves bone mass. Women with POF need HRT until their early 50s. Up to 60 years of age, the benefits of HRT outweigh the risks and mortality is reduced. There are no effective alternatives to oestrogen with long-term safety data for vasomotor symptoms. The role of oestrogen in CVD, dementia and quality of life is currently unclear.
3. With regard to the risks of HRT, the main areas of concern are breast and endometrial cancer and VTE. The increase in risk of breast cancer is approximately equivalent to the increase in relative risk of breast cancer associated with each year the menopause is delayed after 50 years of age. In non-hysterectomized women, progestogen is added to oestrogen to reduce the risk of endometrial cancer. Oral oestrogen, but not transdermal oestrogen, increases the risk of VTE.
4. Non-hormonal treatments for osteoporosis, such as bisphosphonates and strontium ranelate, have mainly been studied in women over 60 years of age at increased risk of the disease. Data for younger women are limited, and these treatments should not be used in women contemplating pregnancy since the effects on the developing fetal skeleton and the long-term consequences are unknown.
5. The evidence that complementary and alternative therapies are effective is poor, and there are concerns about safety and interactions with standard pharmacopoeia.

Fertility control

Catherine A. Schünmann and Anna F. Glasier

Chapter Contents			
INTRODUCTION	422	ABORTION	433
CONTRACEPTION	423	KEY POINTS	437
STERILIZATION	430		

Introduction

Almost everyone will use contraception at some time during their reproductive lives. While contraceptive provision in the UK is largely the role of primary care, obstetricians and gynaecologists should be familiar with all currently available methods and aware of their advantages and disadvantages. They should be able to advise women of the method most appropriate for their individual circumstances, and to deal with the side-effects which lead to referral to a gynaecologist.

Over the last 40 years, there has been a significant increase in the use of contraception worldwide. In 2008, it was estimated that up to 62% of all married women of reproductive age or their partners were using contraception. However, the prevalence of contraceptive use remains low in many less developed countries; only 13% of couples use contraception in some African countries. It has been estimated that some 120 million women in developing/restructuring countries who do not wish to become pregnant are unable, for a variety of reasons, to use contraception (Ross and Winfrey 2002).

In Great Britain, 88% of sexually active women who wish to avoid pregnancy use a method of contraception (Office for National Statistics 2007/8). Usage is lower among adolescents (56%), women over 45 years of age (69%) and less well-educated women (65%).

Worldwide, between 8 and 30 million unplanned pregnancies per year are the result of contraceptive failure. Despite the apparently high prevalence of contraceptive use in the UK, a substantial proportion of births (25.8%) occur among women who were ambivalent regarding pregnancy intention (Lakha and Glasier 2006). Moreover, large numbers of unplanned pregnancies are terminated. Scotland has an abortion rate which is one of the lowest in countries in which abortion is legal, yet for every six babies born, one pregnancy is terminated. Although abortion is a safe procedure in Western countries, it has been estimated that of the annual figure of 42 million abortions performed around

the world, 20 million are unsafe and some 67,000 women die as a result (Facts on Induced Abortion Worldwide, Guttmacher Institute 2009).

The type of contraceptive method used varies around the world. The intrauterine device (IUD) is the most common method in China, while the vast majority of couples in Japan, where the combined oral contraceptive (COC) pill has only been licensed very recently, use the condom. In some of the less developed parts of the world, breast feeding is still the most important method of birth spacing. The prevalence of method use in the UK is shown in Table 29.1; condoms and the pill still prevail. In the UK in the 21st Century, the cost-effectiveness of long-acting reversible contraception (LARC) which relies little, if at all, on compliance for effectiveness has been recognized (National Institute for Health and Clinical Effectiveness 2005). In 2009, the Governments of both Scotland and England launched social marketing campaigns to increase the uptake of LARC. Increasing acceptability of LARC and, particularly, of intrauterine methods of contraception appears to be associated with a dramatic decline in female sterilization in the UK. Increased uptake of contraceptive implants and injections may reduce unintended pregnancies among sexually active teenagers.

Evidence-based recommendations on which individuals can safely use each contraceptive method were first published by the World Health Organization (WHO) in 1996, and are updated at 4-yearly intervals [WHO Medical Eligibility Criteria (WHOME)]. This guidance has been further modified specifically for use in the UK by the Clinical Effectiveness Unit (CEU) of the Faculty of Sexual and Reproductive Healthcare (FSRH) of the Royal College of Obstetricians and Gynaecologists (RCOG), and is available in hard copy and online as the UK Medical Eligibility Criteria (UKMEC). Contraceptive methods are categorized according to their balance of risk and benefit in the presence of certain medical and lifestyle conditions (Table 29.2). Health professionals prescribing contraceptive methods are also directed to the National Institute for Health and Clinical Excellence guidelines on LARC published in 2005.

Table 29.1 Use of contraceptive methods in the UK

Method	%
Combined hormonal contraceptives	18
Progestogen-only pill	6
Implant/injectable	5
Intrauterine device/system	7
Barrier methods	24
Vasectomy	10
Female sterilization	7
Natural family planning	2
Withdrawal	4
No method	25 ^a

Table 29.2 UK Medical Eligibility Criteria for Contraceptive Use (RCOG Press, London, 2009)

Classification categories

1. A condition for which there is no restriction for the use of the contraceptive method
2. A condition where the advantages of using the method generally outweigh the theoretical or proven risks
3. A condition where the theoretical or proven risks usually outweigh the advantages of using the method
4. A condition which represents an unacceptable health risk if the contraceptive method is used

Contraception

Combined hormonal contraceptives

The CHC was approved for use in Britain in 1961. In recent years, different modes of delivery have been developed, with injectable, transdermal and vaginal methods now available in some countries. Although unlikely to be substantially different from the oral preparation in terms of efficacy and safety, they do provide a wider choice of administration which may help to offset the effects of erratic pill taking.

Combined hormonal contraceptives (CHCs) contain oestrogen, usually ethinyl oestradiol, and a synthetic progestogen (progestogen). Most modern pills contain 20–35 µg ethinyl oestradiol with either a second-generation progestogen [norethisterone, levonorgestrel (LNG) or ethynodiol diacetate] or a so-called third-generation progestogen (gestodene, desogestrel or norgestimate). The newest progestogen, drospirenone, has antiandrogenic and antiminer- alocorticoid properties. The 20 µg pills are as effective as the 30 µg pills but, not surprisingly, are associated with poorer cycle control (Akerlund et al 1993).

The traditional CHC regimen involves taking a tablet for 21 days with a 7-day break, thus inducing a withdrawal bleed in order to mimic the body's 'natural' pattern. Variations on this theme include the everyday formulations containing dummy pills so that users do not have to remember to stop and start (common in the USA), 84-day preparations reducing the number of expected withdrawal bleeds from 13 to four per annum, and a continuous version aimed at banishing bleeding altogether. Injectable CHCs are administered intramuscularly every 28 days, with 70% of women experiencing a withdrawal bleed 18–22 days after injection. They are in common use in Latin America. Despite the plethora of transdermal hormone replacement options, there is only one contraceptive patch available. The patch is applied weekly for 3 weeks prior to a patch-free week, and may help to reduce nausea in susceptible individuals (Audet et al 2001). The latest addition to the CHC family is a vaginal ring, 54 mm in diameter and 4 mm in cross-section. It is made of a soft, ethylene-vinyl-acetate copolymer, lasts for 21 days with a 7-day break, and appears to confer more favourable cycle control than other preparations. These longer-acting CHCs may improve compliance.

Combined pills are available in monophasic, biphasic and triphasic preparations. Phasic pills were developed in order to reduce the total dose of progestogen and, by simulating the fluctuating pattern of steroid concentrations in the normal ovarian cycle, in an attempt to produce better cycle control. There is no good evidence that cycle control is superior to that achieved by monophasic pills.

Mode of action

CHCs work primarily by inhibiting ovulation. Exogenous oestrogen inhibits the secretion of follicle-stimulating hormone, while progestogens inhibit the development of the luteinizing hormone (LH) surge. The CHC also alters cervical mucus, rendering it hostile to the passage of sperm, and also causes endometrial atrophy.

CHCs are highly effective (Table 29.3). The failure rates associated with all forms of contraception depend on the inherent efficacy of the method, but also on the potential for incorrect or inconsistent use. Since ovulation is inhibited in most women who use the combined pill, failure rates of the method itself are low. However, as inhibition of ovulation depends on reliable pill taking, the overall failure rate of the COC, which includes user failure, is higher.

Contraindications

In an analysis of 25 years of follow-up of 46,000 women who took part in the Royal College of General Practitioners' (RCGP) Oral Contraceptive Study comparing 517,519 years of pill use with 335,998 years of never-use, the risk of death from all causes was similar in ever-users and never-users of oral contraception (Beral et al 1999). Among current and recent users (within 10 years), the relative risk (RR) of death from ovarian cancer was significantly decreased (RR 0.2), while the risks of dying from cervical cancer (RR 2.5) and cerebrovascular disease (RR 1.9) were increased.

Absolute contraindications to CHC use are listed in Box 29.1. They include either a past history of, or existing,

Table 29.3 Pregnancy rates for birth control methods (for 1 year of use)

Method	Typical use rate of pregnancy (%)	Lowest expected rate of pregnancy (%)

IUD, intrauterine device; IUS, intrauterine system; LNG, levonorgestrel.

This table provides estimates of the percentage of women likely to become pregnant while using a particular contraceptive method for 1 year. These estimates are based on a variety of studies.

'Typical use' rate means that the method was not always used correctly, was not used with every act of sexual intercourse or was used correctly but failed.

'Lowest expected' rates mean that the method failed despite being used correctly with every act of sexual intercourse.

^aUsed without spermicide.

Box 29.1 Absolute contraindications to the COC pill

Arterial or venous thrombosis
 Ischaemic heart disease including myopathy
 Most valvular heart disease
 Past cerebral haemorrhage
 Hypercholesterolaemia
 Conditions predisposing to thrombosis, e.g. polycythaemia
 Migraine
 Pulmonary hypertension
 Active liver disease
 Porphyria
 History of a serious condition affected by sex steroids, e.g. trophoblastic disease

cardiovascular disease, migraine and most liver diseases. Women often describe headaches as migraine. CHCs are contraindicated in migraine which is or may be associated with transient cerebral ischaemia. A recent study designed to investigate the risk between migraine and stroke in young women demonstrated a significant increase in the risk of ischaemic, but not haemorrhagic, stroke in women with a personal history of migraine both with and without aura (classic and simple). Concomitant use of the CHC further increased this risk (Chang et al 1999). It is important therefore to take a clear and detailed history before refusing to prescribe a CHC because the woman has an occasional migraine.

Relative contraindications to CHC use include the following:

- factors which increase the risk of cardiovascular disease or venous thrombosis, such as obesity, smoking, hypertension and family history;
- sex-steroid-dependent conditions, including cancer;
- factors which adversely affect liver function; and
- factors which predispose to arterial wall disease.

Comprehensive discussions and lists of contraindications are available in most textbooks of contraception, and WHOMEK and UKMEC.

Side-effects of combined oral contraception

Debate continues over the increased risk of cardiovascular events in women taking CHCs. Until reliable data are available for non-oral routes of administration, it is sensible to assume that similar risks apply to all methods. Cardiovascular disease is very rare in women of reproductive age. Venous thromboembolism (VTE) is the most common cardiovascular complication of CHC use. Oestrogen and progestogen are both metabolized by the liver and alter the metabolism of most substances, including carbohydrates and lipids. Oestrogens also alter coagulation factors. A reduction in antithrombin III and alteration in platelet function increase the risk of VTE by up to seven-fold. A clear history of thromboembolism is a contraindication to CHCs. A possible history or a very strong family history are indications for investigating haemostasis, particularly circulating concentrations of antithrombin III and the factor

V Leiden thrombogenic mutation. Population screening for inherited thrombophilias is not currently considered to be cost-effective.

Studies in the mid-1990s appeared to show a differential risk of VTE between the second- and third-generation progestogens, the latter being associated with double the risk of the former (Bloemenkamp et al 1995, Jick et al 1995, WHO 1995, Spitzer et al 1996). These findings prompted the UK Committee on Safety of Medicines to advise women at risk of thrombosis to avoid third-generation progestogens. Although well designed, criticisms of these studies include prescriber bias (whereby women with cardiovascular risk factors and new users would be more likely to be prescribed a newer brand) and attrition bias (existing users susceptible to VTE would be less likely to be using older brands). Latterly, the 2005 EURAS study, funded and designed as a postmarketing cohort study to demonstrate the safety of the combined ethinylestradiol/drospirenone pill, found an increased incidence of VTE across the categories (including pregnant women and non-pregnant, non-CHC-using women) with no difference between progestogen used (Dinger et al 2007). Whilst the large numbers in the study (58,674 women and 142,475 women-years) lend strength to its findings, data from the pharmaceutical industry must always be viewed with some reservation. Of additional interest was the reported three-fold increase in risk for women with a body mass index (BMI) above 30 compared with women with a BMI of 20–25. Table 29.4 shows the comparison of risk estimates of VTE from the two sources.

Current CEU advice to prescribers acknowledges the continuing debate over progestogens, and suggests that individual risk of VTE should be a governing principle in choice of contraceptive method.

Arterial disease, including myocardial infarction (MI) and cerebrovascular accident, results from the (mainly) progestogen-related alteration to lipid profiles together with the oestrogen-associated changes in blood coagulation. A WHO expert group reviewed the data on MI, stroke and hormonal contraception; the conclusions are as follows (World Health Organization Scientific Group 1998).

Acute myocardial infarction

- Acute MI is uncommon in women of reproductive age.
- Women who have hypertension and who take the COC have an increased RR of MI of at least three times that of women who take the COC and are normotensive.
- Smoking increases the risk of MI by 10 times when compared with COC users who do not smoke.
- There is insufficient evidence to allow any conclusion on whether the risk of MI is influenced by the type or dose of progestogen.

There was no increased risk of mortality due to ischaemic heart disease, either during or after COC use, in the report of the RCGP study (Beral et al 1999). However, two recent meta-analyses reported odds ratios of 1.84 and 2.48 for MI with low-dose COC use compared with non-current use [Baillargeon et al (2006) and Khader et al (2003), respectively], casting some doubt on WHO's conclusion that the risk of MI is not increased in CHC users who do not smoke or have hypertension or diabetes.

Stroke

- Ischaemic and haemorrhagic stroke are both uncommon among women of reproductive age.
- The risk of ischaemic stroke is increased approximately 1.5-fold in pill users who do not smoke and are not hypertensive. In contrast, the risk of haemorrhagic stroke is not increased in these women until they reach 35 years of age, after which the increasing natural risk of haemorrhagic stroke is magnified by CHC use.
- Hypertension increases the risk of both ischaemic (by three times) and haemorrhagic (10-fold) stroke compared with never-users.
- Smoking increases the risk of ischaemic and haemorrhagic stroke (≈ 2 – 3) compared with pill users who do not smoke.
- There is insufficient evidence to determine whether the risk of either type of stroke is influenced by the type or dose of progestogen.

Thus the data are reassuring for haemorrhagic stroke, but the risk of ischaemic stroke is increased by COC use; once again, this is supported by the findings of the RCGP study (Beral et al 1999), in which the RR of death from stroke was significantly increased to 1.9 [confidence interval (CI) 1.2–3.1, $P = 0.009$]. Ten years after discontinuation of the pill, the risk of death from stroke is no longer elevated. For a useful review of hormonal contraception and cardiovascular risk, see Curtis and Marchbanks (2005).

Cancer

Overviews of the risks and benefits of the COC are dominated by breast cancer. Published data are difficult to interpret because pill formulations and patterns of reproduction (particularly age at first pregnancy) have changed with time. In 1996, the Collaborative Group on Hormonal Factors in Breast Cancer reported a meta-analysis of 54 studies involving over 53,000 women with breast cancer and 100,000 control subjects. The group concluded that use of the COC was associated with a small increase in breast cancer, and that the increased risk persisted for 10 years after discontinuation of the pill. The RCGP study (Beral et al 1999) was also reassuring in this respect, since the risk of dying from

Table 29.4 Absolute risk of venous thromboembolism (VTE)

Population	VTE per 100,000 women-years	
	Committee on Safety of Medicines 1995	EURAS 2005
Non-pregnant, non-user	5	44
Second-generation progestogen COC	15	80 ^a
Third-generation progestogen COC	25	99
Drospirenone	–	91
Pregnant non-user	60	291

COC, combined oral contraceptive.
^aLevonorgestrel alone.

breast cancer was not significantly increased among current or recent (within 10 years) COC users. The relationship between the pill and breast cancer is difficult to explain because the risk appears to increase soon after exposure, does not increase with duration of exposure and returns to normal 10 years after discontinuation. It has been suggested that starting to use the pill may accelerate the appearance of breast cancer in susceptible women (i.e. late-stage promotion of existing dysplasia). It is also possible that women using the pill have their tumours diagnosed earlier, although it is difficult to explain why a tendency to earlier diagnosis would persist for years after discontinuation. In the large meta-analysis, the risk of breast cancer was also increased among current users of both the progestogen-only pill (RR 1.17) and Depo-provera (RR 1.07), although the number of women using progestin-only methods was small. These findings strengthen the argument for increased detection rather than late-stage promotion of breast cancer. Nonetheless, a biological effect of hormonal contraception has still not been ruled out.

Incident data from a large cohort study from the RCGP (Hannaford et al 2007) has shown significantly lower rates of cancers of the large bowel, rectum, uterine body, ovaries and tumours of unknown origin in ever-users of the COC compared with never-users. There was no material difference between groups for breast cancer, and only small, non-statistically-significant increases in cancers of the lung, cervix and central nervous system. Taken together, there was an absolute rate reduction of any cancer in ever-users of 45 per 100,000 women-years.

Conversely, women taking the COC for more than 8 years did have a significantly increased risk of cervical cancer.

An increase in the risk of squamous carcinoma of the cervix (RR 1.3–1.8) has been recognized for some time. Recent extensive analysis of existing data detected an RR of 1.9 for 5 or more years of COC use (90% CI 1.69–2.31), declining after cessation of use and, like breast cancer, no different from that of never-users at 10 years after discontinuation (International Collaboration of Epidemiological Studies on Cervical Cancer 2007). The relationship is complicated by a number of confounding factors such as patterns of sexual behaviour and the likelihood of having cervical smears. Whether the national introduction in 2008 of vaccination for girls against human papilloma virus types 16 and 18 will have an effect on these figures remains to be seen. An increase in the risk of the much less common cervical adenocarcinoma (RR 2.1, increasing to 4.4 after 12 years of use) has also been demonstrated (Ursin et al 1994).

Other side-effects

Approximately 2% of women become clinically hypertensive after starting the pill. The incidence increases with age and duration of use, obesity and family history. It does not, however, appear to be increased in women with a history of pregnancy-induced hypertension.

An increased risk of gallstones is only significant during the early years of pill use.

A few women develop chloasma on the CHC; both oestrogen and progestogen contribute to this. The chloasma may be slow to fade after the hormones are stopped.

Minor side-effects are most common during the first 3 months of use, and often lead to discontinuation of the method. More common problems include breakthrough bleeding (BTB) or spotting, nausea, breast tenderness, acne and loss of libido. Many of these resolve with time. If side-effects persist after 4 months, it is often worth changing the brand of pill, opting for a lower dose of oestrogen or a different type of progestogen, or changing the mode of delivery. Pills containing antiandrogens are particularly useful for acne.

While the CHC, in general, improves menstrual bleeding patterns, one common reason for presentation to a gynaecologist is BTB. BTB is common during the first three cycles of use. Persistence beyond 3 months may be a result of poor compliance or a coexisting gynaecological disorder such as cervical ectropion (probably more common among COC users), or cervical or uterine polyps. If pelvic examination is normal, it is worth trying a formulation containing a higher dose of oestrogen or a different type of progestogen. After 3 months' use of a pill containing 50 µg ethinyl oestradiol, the bleeding will often settle and the woman can then resume a lower-dose pill. Alternatively, the vaginal ring may confer improved bleeding patterns. If bleeding persists, try stopping hormonal contraception altogether; if it does not resolve, it should be investigated as intermenstrual bleeding, i.e. by endometrial biopsy and hysteroscopy.

Benefits of combined oral contraception

The CHC confers a number of health benefits. Withdrawal bleeds are usually more regular, lighter and less painful, and the CHC is often the treatment of choice for women with irregular heavy periods (resulting from anovulatory dysfunctional uterine bleeding), premenstrual syndrome, dysmenorrhoea and endometriosis, as ovarian suppression can be achieved without the need for additional contraception (in contrast to danazol). A Cochrane review also concluded that the CHC can improve acne (Arowojolu et al 2009). These benefits can improve compliance significantly (Courtland Robinson et al 1992).

CHC use is associated with a 70% reduction in the risk of endometrial cancer, which may be maintained for up to 15 years after discontinuation (Weiderpass et al 1999). There is a similar duration-dependent reduction in the risk of ovarian cancer (RR 0.64, 95% CI 0.57–0.73) in ever-users compared with never-users (Riman et al 2004), which probably acts through the inhibition of ovulation and lasts for at least 10 years after discontinuation.

Significant numbers of unplanned pregnancies result from women stopping the pill for a 'break'. There is no evidence that breaks in pill taking reduce the long-term risks. It is not necessary to stop the CHC before planning a pregnancy. There is no evidence of any adverse effect on the fetus of CHC use prior to conception, neither is exposure during pregnancy associated with increased risk of fetal malformation.

Fertility is restored after a delay of 1–3 months, although some women take longer to resume normal cycles. So-called 'post-pill amenorrhoea' is almost always associated with cycle irregularity before starting the pill or with coincidental factors associated with secondary amenorrhoea, such as weight loss or stress.

Progestogen-only contraceptives

Progestogen-only contraceptives (POCs) are much less commonly used than CHCs. However, POCs are available in a wider variety of systems, including pills, implants, long-acting injectables and hormone-releasing IUDs.

The mechanism of action of POCs depends on the dose of steroid administered. High doses, such as depot medroxy-progesterone acetate (DMPA), inhibit ovulation. Low doses only inhibit ovulation inconsistently, and the effect varies between individuals. All POCs affect both the quantity and physical characteristics of cervical mucus, reducing sperm penetrability and transport. All have an effect on the endometrium, probably compromising implantation. The recent addition of a 75 µg desogestrel progestogen-only pill (Cerazette®) combines inhibition of ovulation in 97% of users with the oral route of administration.

The absence of oestrogen in this group of hormonal methods is associated with an absence of cardiovascular risks including VTE. In a case-control study undertaken by WHO (World Health Organization Collaborative Study of Cardiovascular Disease and Steroid Hormone Contraception 1998), there was no significant increase in the risk of MI, stroke or VTE associated with use of oral or injectable progestogen-only methods.

The progestogen-only pill (POP or mini-pill) is a useful alternative for women who like the convenience of the COC but for whom oestrogen is contraindicated. Not only does the POP not contain oestrogen, but the dose of progestogen is significantly lower than in equivalent combined preparations. The POP is still a good alternative for women with medical contraindications to the COC, such as migraine and hypertension. It is often advocated for women with diabetes who are at increased risk of cardiovascular disease and who may find that insulin requirements fluctuate with COC cycles. However, the COC is not absolutely contraindicated for diabetic women without long-term complications, whose diabetes is well controlled and for whom pregnancy would be a disaster. The most common indication for POP use in the UK used to be for breastfeeding women, since the POP (unlike the CHC) does not interfere with either the quantity or constituents of breast milk. However, due to its mode of action and likely increased efficacy, the newest POP has wider potential. It is no longer considered necessary to advise women routinely to change from the COC to the POP when they reach the age of 35 years, since the combined pill, in the absence of risk factors for cardiovascular disease, is very safe.

Mode of action

While Cerazette inhibits ovulation in over 90% of cycles, approximately 50% of classical POP users continue to ovulate and menstruate regularly. In these women, the POP works by altering cervical mucus and probably by interfering with implantation. If follicle development is inhibited completely, amenorrhoea results (10–20% of women).

Side-effects

The mode of action of the POP explains its side-effects. Erratic bleeding is the most common cause for discontinuation of the pill; approximately 20% of women will stop using it for this reason.

Follicular growth without ovulation is associated with an increased incidence of functional ovarian cysts. Up to 20% of women using the POP will have a cyst identifiable by ultrasound. Most are symptomless and nearly all resolve spontaneously. A woman found to have a symptomless ovarian cyst should be reviewed after her next menstrual period.

POP use is associated with a slightly increased risk of ectopic pregnancy. Some 2% of pregnancies among POP failures will be ectopic, perhaps as a result of an effect of the progestogen on tubal motility. Since Cerazette inhibits ovulation in almost all cycles, the theoretical risk of ectopic pregnancy is less.

Due to its mechanism of action (50% of women continue to ovulate) and its relatively short half-life (approximately 19 h), the classical POP has a higher failure rate than the COC (see Table 29.3), with users of the established varieties having a 3-h window within which to remember to take their pill. This failure rate is dependent on age and is almost as low as the COC in women aged over 35 years. However, the ovulation-inhibiting Cerazette can be taken in much the same way as the COC with a 12-h window, making it a suitable and reliable choice for younger women as well. There is no direct evidence for advising women who weigh more than 70 kg to take two pills each day.

Injectable progestogens

Long-acting injectable progestogens are available in two forms: DMPA or Depo-provera (150 mg IM every 12 weeks) and norethisterone oenanthate (200 mg IM every 8 weeks). The latter is seldom used in the UK.

Worldwide, DMPA is a popular method of contraception used by some 9 million women in over 90 countries. DMPA appears to exert a powerful protective effect against endometrial cancer with an RR of 0.2. No association has been described between DMPA use and the risk of ovarian cancer, which is surprising if the protective effect of the COC is due to the inhibition of ovulation. The slight increase in the risk of breast cancer among users of both the POP and DMPA identified in the large meta-analysis (Collaborative Group on Hormonal Factors in Breast Cancer 1996) may be due to detection bias; however, there are some concerns that progestins alone may be associated with a real increase in risk.

Depo-provera is a highly effective (Table 29.3) long-acting method which only requires the user to attend for injection four times a year. It inhibits ovulation, and 80% of women are either amenorrhoeic (40%) or have very scanty, infrequent periods (40%) after 1 year of use. The remaining 20% of women will have prolonged regular or, more usually, irregular bleeding episodes, and approximately 2% of women will present, often to a gynaecologist, with troublesome menorrhagia. After excluding any pathology, the most effective treatment of menorrhagia is oestrogen (Fraser 1983), and it is most easily given as one packet of the COC. If bleeding problems persist, an alternative method of contraception should be considered.

Other significant long-term side-effects include:

- weight gain; up to 6 kg during the first 2 years of use;
- a delay in the resumption of fertility of up to 1 year or more after cessation of use; and
- a reduction in bone mineral density (BMD).

BMD has been shown to plateau after an initial decrease in the first year of use. Current studies (flawed by the use of surrogate measures of bone health, methodological errors, comparison of heterogeneous populations and varying sites of BMD measurements) show a 2–3% decrease in BMD in the first year of DMPA use, slowing in subsequent years. BMD is gradually regained following discontinuation of DMPA, and appears to be similar to that of never-users in adults at 30 months after the last injection (Gbolade et al 1998). Similar findings in adolescents were reported at 12 months after discontinuation of the method (Scholes et al 2005). To date, there is no good evidence for an increased risk of fractures.

The Committee on Safety of Medicines (2006) made the following recommendations in the light of the existing evidence:

- in adolescents, DMPA may be used as a first-line contraception but only after other methods have been discussed with the patient and considered to be unsuitable or unacceptable;
- in women of all ages, careful evaluation of risks and benefits of treatment should be carried out in those who wish to continue use for more than 2 years; and
- in women with significant lifestyle and/or medical risk factors for osteoporosis, other methods of contraception should be considered.

This advice is in line with the UKMEC.

Progestogen-only implants

Progestogen-only, subdermal implants are available worldwide and are used by millions of women. The original LNG-releasing Norplant® comprised six rods; modern implants with a preloaded applicator and only one or two rods are much easier to insert and remove. Jadelle® is identical to Norplant but has two rods. It is approved for 5 years. Implanon®, a single rod, is approved for 3 years of use in the UK, and consists of an ethylene–vinyl–acetate copolymer core containing 68 mg etonorgestrel. The rate-limiting membrane allows an initial release rate of approximately 60–70 µg/day, slowly decreasing to 30–40 µg/day at the end of the second year and 25–30 µg/day at the end of the third year.

Although the implants are not difficult to insert, removal can occasionally be troublesome, particularly if the rods are inserted subcutaneously rather than subdermally. Failure rates are extremely low (Table 29.3), and all failures are due to the method as implants do not depend on compliance. The dose of progestogen is sufficient to inhibit ovulation in every cycle throughout the 3 years. Cervical mucus is scanty and allows poor sperm penetration.

Approximately 20% of women experience amenorrhoea with Implanon. A further 60% may experience erratic bleeding or no effect on their usual menstrual cycle. The remaining 20% will request removal on the basis of unacceptable menstrual disturbance. Fertility resumes as soon as the implants are removed. Bleeding irregularity is the most common side-effect and reason for removal, but others include acne, hirsutism, headache, mood change, and weight gain or bloating (i.e. the metabolic side-effects of progestogens). For a useful review of contraceptive implants, see Glasier (2002).

Intrauterine devices and systems

The IUD is a cheap, effective long-acting method of contraception. It exerts a local inflammatory reaction within the cavity of the uterus which probably, acting through tubal and uterine fluid, interferes with the viability of both sperm and eggs. It also inhibits implantation. Inert devices are no longer recommended or marketed, but some older women do still have them *in utero*. Modern copper-containing devices are licensed for use over 5–10 years. After a woman reaches 40 years of age, the device need not be changed and can be removed 1 year after the last menstrual period. Copper IUDs consist of a plastic frame with copper wire round the stem and, in some cases, copper caps on the arms. The surface area of the copper determines the lifespan and efficacy of the device. IUDs with a surface area of copper of less than 200 mm² are associated with higher pregnancy rates and are no longer recommended for long-term use. A frameless IUD (Gynefix®) comprises six copper beads threaded on to a nylon line. The beads at the top and bottom are crimped to hold them on the line, and the string has a knot at the proximal end which is embedded, using a special inserter, into the myometrium, anchoring it in place.

The LNG-releasing device [known as a system (IUS) to distinguish it from copper IUDs] has been licensed in the UK since 1995 under the trade name Mirena®. It consists of a column of LNG within a rate-limiting membrane wrapped around the stem of a Nova-T frame. A total dose of 52 mg LNG is released at a rate of 20 mg/day. It is licensed for 5 years for contraception. A small amount of LNG is absorbed systemically and can give rise to androgenic side-effects such as acne. Menstrual bleeding is significantly reduced, with periods being replaced by light spotting and eventually, in many women, amenorrhoea. In the classic study of the effects of the LNG-IUS on menstrual blood loss (Andersson and Rybo 1990), women complaining of menorrhagia experienced a reduction in blood loss of 86% at 3 months and 97% at 12 months after LNG-IUS insertion. Mirena is now widely used in the UK, and is licensed for the management of menorrhagia (Royal College of Obstetricians and Gynaecologists 1999) and as the progestogen component of hormone replacement therapy. A frameless equivalent of the IUS, Fibroplant®, is the most recent modification of this technology with a silastic sleeve, suspended on a thread which is anchored into the uterine fundus with a knot.

Side-effects

Perforation is a rare event (one in 1000 insertions); if it is recognized early, it may be possible to remove the IUD via the laparoscope before adhesions form. For this reason, it is probably wise to see women for follow-up to check the tails of the device within 4–6 weeks of insertion.

Expulsion occurs in 3–10% of women in the first year of use and is related to parity, age, type of IUD and timing of insertion. The incidence of both expulsion and perforation is influenced by the skill of the person inserting the device. Both complications are increased with postpartum insertions which, according to the UKMEC, should be scheduled no earlier than 4 weeks after delivery.

The risk of pelvic infection among IUD users has been greatly exaggerated. In countries where IUDs are inserted under appropriate sterile conditions, the risk of pelvic infection is only increased for 20 days after insertion. Women infected with gonorrhoea or chlamydia have an increased risk of infection if an IUD is inserted compared with uninfected women, but the risk of salpingitis is not increased compared with infected women who are not undergoing IUD insertion. Even women who are human immunodeficiency virus (HIV) positive do not appear to have an increased risk of complications, including infection, associated with IUD insertion, and there is no evidence that IUD use increases viral shedding (Grimes 2000). In addition, there is no evidence for an increased risk of infertility among past or current IUD users. However, if an IUD user becomes pregnant, the probability of that pregnancy being ectopic is greater than that for women using no contraception or another method because the IUD does not prevent tubal implantation. In women at risk of pre-existing infection, IUD insertion can be covered with a broad-spectrum antibiotic. Routine screening for infection may be more cost-effective in services where the background rate of infection, especially with chlamydia, is high.

The most common reason for discontinuation of the copper IUD is menorrhagia. The local inflammatory response, together with increased production of prostaglandins, causes both menorrhagia and dysmenorrhoea. All IUDs are removed by steady traction on the tail of the device. Occasionally, the string snaps off during removal. It is sometimes possible to remove the device with a pair of artery forceps or a specially designed IUD remover, but some IUDs, particularly the old inert devices, appear to become deeply embedded in the endometrium and may only be removed under general anaesthetic. It is not known if an IUD without its tails can be left in the cavity of the uterus for a woman's lifetime without causing any problems. There is a small risk of actinomycosis but the inconvenience of admission to hospital for a general anaesthetic may outweigh this. It is probably best discussed with the individual concerned.

Natural family planning

Although few couples in the UK use so-called 'natural methods of family planning' (NFP), these methods are common in some parts of the world. All involve 'periodic abstinence' (i.e. avoidance of intercourse during the fertile period of the cycle). Methods differ in the way in which they recognize the fertile period. The simplest is the calendar or rhythm method, in which the woman calculates the fertile period according to the length of her normal menstrual cycle. Others use symptoms which reflect fluctuating concentrations of circulating oestrogen and progesterone, themselves reflecting follicular development, impending ovulation and completed ovulation. The mucus or Billings method relies on identifying changes in the quantity and quality of cervical and vaginal mucus as a reflection of the steroid environment. As circulating oestrogens increase with follicle growth, the mucus becomes clear and stretchy, allowing the passage of sperm. With ovulation and in the presence of progesterone, mucus becomes opaque, sticky and much less stretchy or disappears altogether. Intercourse must stop

when fertile-type mucus is identified, and can start again when infertile-type mucus is recognized. Progesterone secretion is also associated with a rise in basal body temperature (BBT) of approximately 0.5°C. The BBT method is thus able to identify the end of the fertile period. Other signs and symptoms such as ovulation pain, position of cervix and degree of dilatation of the cervical os can also be used to help define the fertile period. A personal fertility monitor called Persona, which measures urinary oestrogen and LH using a dipstick, can help to identify the fertile period but does not significantly reduce the number of days of abstinence required and is expensive. Whatever method is used, all rely on a period of abstinence and many couples find this difficult. Failure rates are high (Table 29.3) and most of the failures are due to conscious rule breaking. Perfect use of the mucus method is, in fact, associated with a failure rate of only 3.4%. There is no evidence that accidental pregnancies occurring among NFP users, which are conceived with ageing gametes, are associated with a higher risk of congenital malformations.

Lactational amenorrhoea method

Breast feeding delays the resumption of fertility, and it still has a major impact on fertility rates in developing countries. It has been calculated that breast feeding provides more than 98% protection from pregnancy during the first 6 months post partum if the mother is fully or nearly fully breast feeding and has not yet experienced vaginal bleeding after the 56th day post partum. Lactational amenorrhoea method (LAM) guidelines advise that as long as the baby is less than 6 months old, a woman can rely on breast feeding alone until she menstruates or until she starts to give her baby significant amounts of food other than breast milk. Prospective studies of the LAM confirm its effectiveness (Perez et al 1992).

Barrier methods

The male condom remains one of the most popular methods of contraception in the UK. It is cheap, widely available over the counter and, with the exception of the occasional allergic reaction, is free from side-effects. Use of the condom increased significantly with concern over the spread of HIV and acquired immunodeficiency syndrome as it is the only method of contraception which also prevents sexually transmitted infections (STIs).

In addition to protection against STIs, use of the condom, and diaphragm, is associated with a significant reduction in cervical disease (Celentano et al 1987). Female barrier methods are less popular. The diaphragm and cervical cap must be fitted by a professional and do not confer the same degree of protection against STIs/HIV. The female condom, by virtue of covering the mucus membranes of the vagina and vulva, is more effective in preventing STIs but has a high failure rate and low acceptability.

Spermicides alone are not a very effective method of contraception and are only recommended for use with a condom (most of which are already lubricated with spermicide) or diaphragm. Nonoxynol 9 (N-9) is a spermicidal product sold as a gel, cream, foam, film or pessary for use with diaphragms or caps. Many male condoms are

lubricated with N-9. As frequent use of N-9 might increase the risk of HIV transmission, women who have multiple daily acts of intercourse or who are at high risk of HIV infection should not use N-9. For women at low risk of HIV infection, N-9 is probably safe (Van Damme et al 2000, www.who.int).

Emergency contraception

Hormonal preparations and the IUD can be used to prevent pregnancy after intercourse has taken place. In the UK, one hormonal preparation is available: Levonelle (LNG 1.5 g). It is licensed for use within 72 h of intercourse, but women should be encouraged to present as soon as possible for treatment. It is, in any case, very difficult to estimate the efficacy of any emergency contraceptive (EC) since the true risk of pregnancy for any one individual cannot be calculated with any degree of certainty, and many of the 'failures' are pregnancies which are, in fact, conceived with an act of intercourse which occurred earlier in the cycle or some time after the act for which EC was sought. Levonelle is now available off prescription from pharmacists.

IUD insertion is more effective (Table 29.3) and can be used up to 5 days after the estimated day of ovulation, which may be significantly longer than 5 days after the act of intercourse. The FSRH advise that intrauterine EC should be offered to all women presenting after unprotected intercourse, in the absence of contraindications, as the gold standard method. If the woman does not wish to continue with the method, it can be removed with the next period or when an alternative method has been established.

The mechanism of action of hormonal EC remains unclear. It has been shown to delay or impair ovulation in some 50% of users, but there is no good evidence that it will inhibit implantation. Neither is there any contraceptive/contragestive effect once implantation is complete. Conversely, the IUD has a toxic effect on gametes, reduces the number of sperm reaching the fallopian tubes and, if inserted after fertilization has taken place, inhibits implantation, resulting in a higher level of efficacy (Table 29.3). The LNG-IUS is not recommended as an emergency contraceptive.

Recent efforts to find a more effective, orally active emergency contraceptive with fewer side-effects have resulted in trials of the antiprogesterone mifepristone (Task Force on Postovulatory Methods of Fertility Regulation 1999). Since mifepristone is known to inhibit both ovulation and implantation, it is likely to be more effective than LNG, but its properties as an abortifacient limit its further development at present.

Sterilization

Over 42 million couples worldwide, the majority of whom live in developing countries (particularly China and India), rely on vasectomy. More than three times that number rely on female sterilization. In Britain, surgical methods of contraception are declining in popularity. Between 1998 and 2008, vasectomy fell from 12% to 10% and female sterilization fell from 12% to 7%. The more pronounced decline in female sterilization is probably due to the introduction of long-acting reversible methods.

Female sterilization

Female sterilization usually involves the blocking of both fallopian tubes either by laparotomy or minilaparotomy or, more commonly, by laparoscopy. It may also be achieved by bilateral salpingectomy (or by hysterectomy when there is coexistent gynaecological pathology such as hydrosalpinx or fibroids) or by hysteroscopic techniques.

Minilaparotomy and laparoscopic female sterilization are probably equally safe and effective; however, the latter allows sterilization to be done as a daycase procedure and is recommended by the RCOG (2004a) as the method of choice in the UK. Minilaparotomy is most commonly used when sterilization is performed immediately post partum as, at that time, the uterus is large, the pelvis is very vascular and the risks of laparoscopy are increased.

A variety of techniques exist for occluding the tube, as follows.

Ligation

Ligation is used when laparotomy or minilaparotomy are performed. The tubes can be tied with absorbable or non-absorbable sutures, and the ends can be left free or buried in the broad ligament or uterine cornu. Postpartum sterilization is associated with a higher failure rate.

Electrocautery

With electrocautery, one or more areas of the tube are cauterized by diathermy. Bipolar diathermy only allows the tissues held between the jaws of the forceps to be cauterized. The temperature of the cauterized tube may reach 300–400°C and, if allowed to touch adjacent structures, can cause local burns. Failure to cauterize all the layers of the tube results in a relatively high failure rate (2–5/1000), and cautery close to the cornual portion of the tube is thought to increase the risk of ectopic pregnancy. The RCOG (2004a) only recommends the use of diathermy if tubal occlusion proves to be difficult and mechanical methods have failed.

Falope ring

A ring of silicone rubber is placed over a loop of tube with a specially designed applicator. The ring destroys 2–3 cm of tube and may be difficult to apply if the tube is fat or rigid. As ischaemia of the loop causes significant postoperative pain, application of topical anaesthesia during sterilization is recommended.

Clips

A variety of clips are available. They destroy a much smaller length of tube, allowing easier reversal, but special care must be taken to ensure that the whole width of the tube is occluded. The Hulka–Clemens clip (stainless steel and a polycarbonate) and the smaller Filshie clip (titanium lined with silicone rubber) are probably the most commonly used in the UK.

Laser

Laser vaporization can be used to divide the tubes; however, the carbon dioxide laser divides them very cleanly

and may allow a high incidence of recanalization. The neodymium:yttrium aluminium garnet laser, although probably more effective, is extremely expensive.

Efficacy

A report from the US Collaborative Review of Sterilization (Peterson et al 1996) prospectively evaluated over 10,000 women who underwent sterilization in nine US cities. The women were followed-up for between 8 and 14 years. The failure rate varied with age and the method of tubal occlusion. The 10-year lifetable cumulative probability of pregnancy for all ages combined (18–44 years) ranged from 7.5 pregnancies per 1000 procedures (for unipolar coagulation and postpartum partial salpingectomy) to 36.5 pregnancies per 1000 procedures (for clips). Failure rates were highest for women under the age of 28 years, with 52 pregnancies per 1000 procedures for spring clips. Women considering laparoscopic sterilization in the UK should be advised that the lifetime risk of failure is one in 200.

In the UK, a device called Essure® is the only licensed product available for hysteroscopic sterilization. It is a 4 cm, inert, nickel-titanium coil containing polyester fibres, designed to be inserted into each tubal ostia under direct vision and to cause fibrosis sufficient to have occluded the tubes by 3 months post procedure. A recent UK cohort study comparing Essure (developed as an 'office-based' procedure) with laparoscopic sterilization reported high levels of patient satisfaction (Duffy et al 2005). Longer-term assessment of efficacy and safety is awaited.

A number of chemical agents have been tested for their ability to occlude the fallopian tube when instilled into the tube either directly or transcervically into the uterus. The quinacrine pellet is the only one ready for large-scale use. The method involves insertion of a 252 mg quinacrine pellet into the uterine cavity through a modified IUD inserter passed through the cervical canal. Two insertions, 1 month apart, are made during the follicular phase of the cycle. Occlusion is caused by inflammation and fibrosis of the intramural segment of the tube. Efficacy can be increased by adding adjuvants such as antiprostaglandins or by increasing the number of quinacrine insertions. A failure rate of 2.6% after 1 year of follow-up has been reported (Hieu et al 1993). The method is cheaper than surgical sterilization, avoids the use of any anaesthesia and can be performed by non-medical personnel. Large numbers of women in Asia and Pakistan have been sterilized using this method. However, although quinacrine is widely used for malaria prophylaxis, the safety of quinacrine sterilization has not yet been determined and some question the ethics of using a technique which has not been approved in developed countries. Toxicology studies are presently underway.

Counselling for sterilization

Most couples seeking sterilization have been thinking about the operation for some considerable time. The initial consultation should include a discussion of:

- the procedure involved;
- the failure rate;
- the risks and side-effects;
- the possibility of wanting more children;
- which partner should be sterilized;
- the issue of reversibility. Despite careful counselling, a few couples will inevitably request reversal of sterilization. This is most likely to happen with remarriage. Immediate postpartum or postabortion sterilization is more likely to be regretted and should be avoided if possible. Although as many as 10% of couples regret being sterilized, only 1% of these will request reversal; and
- alternative long-acting methods of contraception which are reversible and equally effective, such as contraceptive implants.

The RCOG (2004a) recommends that verbal counselling advice should be backed up by accurate impartial printed information which the couple may take away.

Reversal of female sterilization is more likely to be successful after occlusion with clips which have been applied to the isthmus portion of the tube, since only a small section of tube will have been damaged. Patients should realize that reversal involves laparotomy, does not always work (microsurgical techniques are associated with approximately 70% success) and carries a significant risk of ectopic pregnancy (up to 5%). Ovulation should be confirmed and a normal semen analysis should be obtained from the partner before reversal is undertaken. Reversal is unlikely to be available on the National Health Service (NHS) in most parts of the UK.

The history should include the following:

- the reason for the request: some women seek sterilization as a cure for menstrual dysfunction, sexual problems or abdominal pain;
- gynaecological and obstetric history, and relevant medical histories of both partners;
- ages, occupations and social circumstances of both partners;
- numbers, ages and health of their children;
- previous and current contraception and any problems experienced. Some women request sterilization because they are unable to find any other acceptable method of contraception; this is not a good reason for sterilization;
- the stability of the relationship and the possibility of its breakdown; and
- the quality of the couple's sex life.

It is seldom possible to arrange sterilization for a particular time of the cycle, and women should be told to continue using their current method of contraception until their operation. It is not necessary to stop the combined pill before sterilization as the risk of thromboembolic complications is negligible.

If an IUD is *in situ*, it should be removed at the time of sterilization, unless the operation is being done at mid-cycle and intercourse has taken place within the previous few days, in which case it can be removed after the next menstrual period.

Complications

Immediate complications

- The operation carries a small operative mortality of less than eight per 100,000 operations. In a large series

from the USA (Peterson et al 1983), the most common cause of death was anaesthesia. In the UK, laparoscopic sterilization is commonly performed under general anaesthesia, but local anaesthesia is an acceptable alternative.

- Vascular damage or damage to bowel or other internal organs may occur during the procedure and is usually recognized at the time of operation. Nevertheless, patients should be aware that the rare possibility of a laparotomy and longer hospital stay does exist.
- Gas embolism.
- Thromboembolic disease is rare, but is more likely if the procedure is done immediately post partum.
- Wound infection.
- Postoperative pain is common because of local tissue ischaemia and necrosis at the site of occlusion of the tube. It can be reduced by the use of local tubal anaesthesia.

Long-term complications

- Menstrual disorders: women who stop using the combined pill will almost certainly notice that their periods become heavier, perhaps more painful and less predictable, and they should be warned of this. In contrast, women whose previous method of contraception was an IUD will notice an improvement in their bleeding patterns. Although a review of the evidence concluded that female sterilization does not alter ovarian activity or menstruation (Gentile et al 1998), a number of studies have demonstrated an increased incidence of gynaecological consultation and an increased incidence of hysterectomy among women who have been sterilized (Hillis et al 1998). Bearing in mind the inevitable changes in menstrual bleeding patterns associated with advancing age and with discontinuation of the combined pill (the most commonly used method of reversible contraception), it may be that women who have been sterilized are more likely to seek hysterectomy, or more willing to accept it, if they are already incapable of further child bearing.
- The term 'post-tubal sterilization syndrome' was coined to describe a variety of symptoms that have been reported after sterilization and which women may attribute to the procedure. These symptoms include abdominal pain, dyspareunia, exacerbation of premenstrual syndrome or dysmenorrhoea, and emotional and psychosexual problems. Laparoscopy fails to demonstrate any pathology. A review of the literature (Gentile et al 1998) concluded that sterilization is not associated with an increased risk of these problems, except among young women sterilized before 30 years of age in whom the symptoms may sometimes be a manifestation of regret.
- Psychological and psychosexual problems are rare; when they do arise, they tend to do so in those who have had problems before sterilization. Many studies, in fact, report a better mental state after sterilization.
- Bowel obstruction from adhesions is a very rare complication.
- Ectopic pregnancy is a well-recognized complication of sterilization. In the US Collaborative Review (Peterson

et al 1997), the risk was influenced by age and the method of occlusion. The 10-year cumulative probability of ectopic pregnancy for all ages combined ranged from 1.5 (for postpartum partial salpingectomy) to 17 (for bipolar coagulation) pregnancies per 1000 procedures, while for women aged less than 30 years, the figures were 1 and 33, respectively. Women should be advised that if they miss a period and have symptoms of pregnancy, they should seek medical advice urgently.

Vasectomy

Vasectomy involves the division or occlusion of the vas deferens to prevent the passage of sperm. The vas is exposed through a small skin incision, and ligated or occluded with small silver clips or by unipolar diathermy with a specially designed probe which can be passed into the cut end of the vas.

Excising a small portion of the vas makes reversal more difficult and probably does not increase the effectiveness unless at least 4 cm is removed. It does allow histological confirmation of a correct procedure in difficult cases, but is not routinely recommended. Interposing the fascial sheath between the cut ends or looping the cut ends of the vas back on itself may increase effectiveness. The RCOG (2004a) recommends that fascial interposition or diathermy should accompany division of the vas which, on its own, is not an acceptable technique in terms of the failure rate. This recommendation, although the opinion of experts, is not supported by scientific evidence, and the relative efficacy of any one method of occlusion and efficacy probably depends most on the skill of the surgeon.

The 'no-scalpel' vasectomy (NSV), developed in China in 1974, is now quite widely used. It makes use of specially designed instruments for isolating and delivering the vas through the scrotal skin, and substitutes a small puncture for the skin incision. Any of the standard methods of occlusion may be used. NSV is quick and associated with a lower incidence of infection and haematoma. A comparison between NSV and conventional vasectomy in Thailand reported a complication rate of 0.4% vs 3.1% (Nirapathpongpon et al 1990).

Percutaneous injection of sclerosing agents, such as polyurethane elastomers, or occlusive substances, such as silicone, is also being used in China. The technique avoids any skin incision, the silicone plug is said to be easily removed, and pregnancy rates of 100% up to 5 years after vasectomy reversal have been claimed.

The rate at which azoospermia is achieved depends on the frequency of ejaculation. In the UK, seminal fluid is examined after 12 and 16 weeks, and if sperm are still present, usually monthly thereafter. When sperm are absent from two consecutive samples, the vasectomy can be considered complete; until then, an alternative method of contraception must be used. Approximately 3% of men do not become azoospermic and the vasectomy has to be redone.

Complications of vasectomy

Local complications

Wound infection will occur in up to 5% of men and scrotal bruising is unavoidable. Postoperative bleeding will

be sufficient in 1–2% of men to cause a haematoma, and perhaps 1% of these will require admission to hospital.

Sperm granulomas

Small lumps may form at the cut ends of the vas as a result of a local inflammatory response to leaked sperm. They can be painful and may need excising. Their presence may also increase the chance of failure.

Chronic intrascrotal pain and discomfort (postvasectomy syndrome)

Some men complain of a dull ache in the scrotum which may be exacerbated by sexual excitement and ejaculation. The symptoms are probably due to distension and granuloma formation in the epididymis and vas deferens. Pain may also result from scar tissue forming around small nerves. Chronic pain associated with progressive induration, tubular distension and granuloma formation in the epididymis may require excision of the epididymis and obstructed vas deferens.

Late recanalization

Failure can occur up to 10 years after vasectomy despite two negative samples of seminal fluid following the procedure. It is rare (one in 2000).

Antisperm antibodies

Most men develop detectable concentrations of autoantibodies, presumably as a result of leakage of sperm, some time after vasectomy. Their presence may compromise fertility if reversal is attempted.

Cardiovascular and autoimmune disease

Concerns about a possible link between vasectomy and cardiovascular disease were raised in the 1970s following reports that vasectomy increased atherosclerosis in monkeys, perhaps as a consequence of increased levels of autoantibodies. Several large studies, including a cohort study in the USA of over 10,000 vasectomized men, failed to substantiate increased rates of 98 diseases (McDonald 1997).

Cancer

Two studies from the USA and Scotland suggested an increased risk of testicular cancer following vasectomy. However, a large cohort study of over 73,000 men in Denmark (Moller et al 1994) demonstrated no increase in the incidence of testicular cancer among men who had a vasectomy.

A number of reports from the USA have also suggested an increased risk of prostate cancer following vasectomy. No known biological mechanism can account for any association or causal relationship between vasectomy and prostate cancer. A 1998 systematic review of 14 studies published from 1985 to 1996 (Bernal-Delgado et al 1998) reported a summary risk estimate of 1.23 (95% CI 1.01–1.49), but the authors concluded that there was evidence against a causal relationship. An editorial from the US National Cancer Institute, commenting on a large US population-based study which found no effect of vasectomy on prostate cancer (Peterson and Howards 1998), concluded that vasectomy does not appear to cause prostate cancer or there is only a relatively weak relationship.

Reversal

Reversal of vasectomy is technically feasible in many cases, with patency rates of almost 90% being reported in some series. Pregnancy rates are much less (up to 60%), perhaps as a result of the presence of antisperm antibodies.

Abortion

After the Abortion Act was passed in the UK in 1967, there was a rapid rise in the number of abortions, which reached a plateau in the late 1980s. Since then, there has been a gradual rise in the numbers each year, with 198,500 abortions being performed in England and Wales and 13,700 being performed in Scotland in 2007. The abortion rate in Britain (13 per 1000 women aged 15–45 years in Scotland and 18 per 1000 in England and Wales in 2007) is relatively low compared with many other developed countries. Nevertheless, at least one-third of British women will have had an abortion by the age of 45 years. The rate of teenage pregnancy (including both childbirth and abortion) in Britain is one of the worst in Europe. The Teenage Pregnancy Independent Advisory Group was formed in England 1998 to investigate teenage pregnancy and to make recommendations based on their findings. Their annual reports and the Government's response can be found at www.everychildmatters.gov.org.

Legal aspects

In the UK, it is illegal to induce an abortion except under specific indications, as defined by law. The conditions of the 1967 Abortion Act state that abortion can be performed if two registered medical practitioners, acting in good faith, agree that the pregnancy should be terminated on one or more of the following grounds.

- The continuance of the pregnancy would involve risk to the life of the pregnant woman greater than if the pregnancy were terminated.
- The termination is necessary to prevent grave permanent injury to the physical or mental health of the pregnant woman.
- The pregnancy has NOT exceeded its 24th week and the continuance of the pregnancy would involve risk, greater than if the pregnancy were terminated, of injury to the physical or mental health of the pregnant woman.
- The pregnancy has NOT exceeded its 24th week and the continuance of the pregnancy would involve risk, greater than if the pregnancy were terminated, of injury to the physical or mental health of the existing child(ren) of the family of the pregnant woman.
- There is a substantial risk that if the child were born it would suffer from such physical or mental abnormalities as to be seriously handicapped.

In 1990, the law was amended to reduce the upper limit from 28 to 24 weeks of gestation, reflecting the lowering of the limits of fetal viability resulting from advances in neonatal care. An exception was made in the case of a fetus with severe congenital abnormality incompatible with life (e.g. anencephaly), in which case there is no upper limit.

The 1967 Abortion Act does not apply to Northern Ireland where abortion is only legal under exceptional circumstances, such as to save the life of the mother.

The law recognizes that some doctors have ethical objections to abortion. Doctors who do have objections are obliged to refer women to a colleague who does not hold similar views.

Over 98% of induced abortions in Britain are undertaken on the grounds that the continuance of the pregnancy would involve risk to the physical or mental health of the pregnant woman.

Provision of services

In Scotland and north-east England, over 90% of abortions are performed in NHS hospitals, while in other areas of England, the majority are carried out in private clinics or by charities. In Scotland, abortion accounts for over 22% of the inpatient gynaecological workload and is thus a major issue for gynaecologists. Some hospitals have dedicated services which are quite separate from the general gynaecological service, and which are staffed by experts who are more sensitive and sympathetic. While this has obvious advantages for individual patients and is recommended as best practice by the RCOG (2004b), the approach risks separating abortion from other aspects of reproductive health care and removing it from general gynaecological training. Without exposure during their training to the issue and to women who are seeking abortion, doctors may become increasingly reluctant to be involved with the provision of services, as they are in the USA.

Counselling

Faced with the news of an unintended pregnancy, many women are emotionally devastated and the decision to have a pregnancy terminated is never an easy one. In the UK, the Committee on the Working of the Abortion Act (the Lane Committee), reporting in 1974, recommended that every woman should have the opportunity to have adequate counselling before deciding to have her pregnancy terminated. Abortion counselling should provide opportunities for discussion, information, explanation and advice in a manner which is non-judgemental and non-directional.

By the time most women see a gynaecologist, they have already seen one doctor (usually their general practitioner) and are certain of their decision. However, in order to satisfy themselves that there are grounds for termination, gynaecologists should nonetheless discuss the reasons why the pregnancy is unwanted and whether the woman is absolutely certain about her decision, since uncertainty may be more likely to lead to regret. The woman should be encouraged to think of the practical and emotional consequences of all the possible options of abortion, continuing with the pregnancy and adoption.

Not all doctors are sympathetic, and women who are seen to have conceived because of a true method failure are more likely to get a sympathetic hearing. Many women feel that they have to 'make the case' to the gynaecologist for having their pregnancy terminated, and some will claim method failure even when they have not been using contraception. One in five women who have had an abortion will present

for another at some time in their lives. Women who seem to use abortion as a method of contraception and present again and again probably need psychiatric help and not a punitive approach from the gynaecologist.

In the UK, approximately 1% of women will present too late for legal abortion. These, and some of those who choose to have the baby, will need information about adoption and benefits, and sometimes referral to social services.

The gynaecologist should provide information about the procedure involved, offering, where available and appropriate, a choice of surgical or medical methods to women below 12 weeks of gestation. The possible complications and long-term side-effects of the abortion should also be discussed, together with the implications for future pregnancies. Verbal discussions should be supported by written information, and confidentiality should be emphasized.

Future contraceptive plans are usually discussed before the abortion is carried out. Although this may not be the best time, it may be one of the few opportunities to discuss contraception as many patients do not attend for follow-up.

Assessment

After it has been decided that there are grounds for abortion, it is important to make a careful medical assessment of the woman.

- The medical history should pay particular attention to conditions such as asthma which may influence the choice of method of abortion.
- The stage of gestation should be determined by menstrual history and transvaginal or transabdominal ultrasound scan. Whilst acceptable to establish gestation, pelvic examination for this purpose alone has generally been superseded by ultrasound, as the former is felt to be less accurate and seldom detects ectopic pregnancy or missed miscarriage.
- Whether the service chooses to screen for genital tract infection, particularly chlamydia, or simply to treat everyone with prophylactic antibiotics will depend on the background incidence of infection in the local population, but one or other is essential. If screening is chosen, it is emphasized that antibiotic therapy should be started before abortion is performed.
- Women considered to be at high risk of hepatitis B or HIV should be offered screening with appropriate counselling. Women who refuse screening should be treated as high risk during the abortion procedure.
- Cervical screening should be offered in accordance with national screening policies.
- Blood should be collected for measurement of haemoglobin concentration, and the blood group should be determined. All women who are Rhesus negative should be injected with anti-D immunoglobulin prior to or within 48 h of the abortion to prevent the development of Rhesus isoimmunization.

Techniques of abortion

In general, the earlier the abortion is done, the safer it is. Mortality and morbidity associated with the procedure

increase with the gestation of the pregnancy at the time of termination. The risk of major complications doubles when termination is carried out at 15 weeks of gestation compared with 8 weeks.

The method of choice depends on gestation, parity, medical history and the woman's wishes. The RCOG (2004b) state that, as a minimum, all services must be able to offer abortion by one of the recommended methods for each gestation band, but that services should ideally be able to offer a choice.

Early-first-trimester abortion (≤ 9 weeks)

Surgical

Vacuum aspiration has been the method of choice for early surgical termination of pregnancy in industrialized countries for over 20 years. Dilatation and curettage requires more cervical dilatation and is associated with a significantly higher complication rate, including uterine injury, and a higher incidence of retained products of conception and adverse future reproductive outcome (Henshaw and Templeton 1993).

Vacuum aspiration can be performed under either local paracervical block or general anaesthesia. Some evidence suggests that the use of general anaesthesia increases the risk of the procedure. In the USA, the mortality rate is two to four times greater when general anaesthesia is used rather than local anaesthesia for first-trimester abortion. Preoperative treatment with a cervical priming agent has been shown to reduce the risk of haemorrhage and genital tract trauma associated with vacuum aspiration. Prostaglandins, bougies and mifepristone are all effective, but prostaglandins (gemeprost 1 mg vaginally or misoprostol 400 μ g vaginally, both 3 h before surgery) probably achieve their effect more quickly. Pretreatment of the cervix adds to the cost of the procedure and may be difficult to organize when abortion is performed as a day case. As cervical trauma is more common in women under the age of 17 years and uterine perforation is associated with increasing parity and increasing gestation, efforts to arrange cervical ripening should be concentrated on young women (aged <18 years), highly parous women and those presenting at a gestation of greater than 10 weeks.

A curette of up to 10 mm internal diameter is passed through the cervix, and the contents of the uterus are aspirated using negative pressure created by a pump. It is advisable to use the smallest diameter curette which is adequate for the gestation; most gynaecologists use an 8 mm curette at 8 weeks, 10 mm at 10 weeks, etc.

Vacuum aspiration at this stage of pregnancy is extremely safe and effective. Failure is more likely to occur before 7 weeks of gestation when it is possible to miss the fetus with the curette. For this reason, medical methods or a rigorous protocol for early surgical abortion are recommended. The mortality from vacuum aspiration in the first trimester is less than approximately one in 100,000; considerably less than the maternal mortality from continuing pregnancy.

Medical

Medical abortion is available to women in the UK up to 63 days of amenorrhoea (9 weeks of gestation) using a combi-

nation of the antiprogesterone mifepristone 600 mg orally followed 36–48 h later by the prostaglandin gemeprost 1 mg vaginally. Mifepristone is a synthetic steroid which blocks the action of progesterone by binding to its receptor. It also binds to the glucocorticoid receptor and blocks the action of cortisol. When mifepristone is used alone, complete abortion only occurs in approximately 60% of pregnancies. The rate of complete abortion rises to over 95% if a prostaglandin is given 36–48 h after the administration of mifepristone. The antiprogesterone itself stimulates some uterine contractility, but mainly works by greatly enhancing the sensitivity of the myometrium to the tocolytic effect of prostaglandins. A 200 mg dose of mifepristone is as effective as 600 mg and, given with an oral prostaglandin misoprostol (which is not licensed for abortion) 800 μ g vaginally 36–48 h later, makes for a much cheaper and now commonly used regimen.

Offered the choice of method, approximately 30% of women in Scotland prefer medical abortion. Women often choose the medical method because it avoids an anaesthetic in most cases, and because they feel more in control of the situation. It is, however, a two-stage procedure which other women find a disadvantage. The incidence of serious complications is probably similar to that associated with surgical abortion, but because 95% of women need neither anaesthesia nor instrumentation of the uterus, large randomized trials may eventually show medical abortion to be safer. Not all women are suitable for medical abortion; the contraindications are shown in Box 29.2.

There are very few side-effects following administration of mifepristone. The fetus is usually passed within 4 h of prostaglandin administration, and this is accompanied by bleeding and pain. The bleeding is usually described as being like a very heavy period, although rarely ($<1\%$) there may be very heavy bleeding requiring resuscitation. Nulliparous women and those with a history of dysmenorrhoea are more likely to experience severe pain, and 10–20% of women may need opiate analgesia. The rest will cope with paracetamol. Prostaglandin synthetase inhibitors, such as aspirin or mefenamic acid, should be avoided for obvious reasons. A few women will abort at home in response to mifepristone with variable amounts of bleeding and discomfort.

Box 29.2 Contraindications to medical abortion

Absolute contraindications

- Adrenal insufficiency
- Ectopic pregnancy
- Asthma
- Cardiac disease
- Heavy smoker
- Older than 35 years
- On anticoagulants or bleeding disorder

Relative contraindications

- Heavy smoker
- >35 years
- Obesity
- Hypertension (diastolic >100 mmHg)

Bleeding can continue for up to 20 days after the abortion, although most women have usually stopped after 10 days. The total amount of blood lost is similar to that occurring at the time of vacuum aspiration.

All women should be given an appointment for follow-up approximately 2 weeks after administration of the prostaglandin. This visit is absolutely essential for those (approximately 30%) who have not passed an identifiable fetus and/or placental tissue while in hospital. Although ongoing pregnancy occurs in only 1% of cases, evacuation of the uterus will be necessary in approximately 2–5% of cases because of incomplete or missed abortion. These figures are no different from those associated with surgical abortion.

The risk of fetal malformation following mifepristone alone or in combination with prostaglandins is not known. Women should be clearly advised that medical abortion is a two-stage procedure, and that it is not possible to have a change of heart after taking mifepristone and before prostaglandin administration. Women who seem even remotely uncertain about abortion should certainly not be offered the medical method. In the event of failed medical abortion and therefore ongoing pregnancy, the patient must be strongly advised to have vacuum aspiration, although babies born to the few women who have chosen to continue with the pregnancy after medical abortion has failed have been normal.

Late-first-trimester abortion (9–13 weeks)

At this stage of pregnancy, the method of choice used to be vacuum aspiration as failure rates for medical methods were thought to be higher. However, a randomized trial of women between 9 and 13 weeks of gestation to either medical or surgical abortion found completed abortion rates to be comparable (Ashok et al 2002). This is reflected in the RCOG guidelines (2004b) which detail an effective medical regimen for this purpose. Surgical evacuation is a straightforward procedure up to 12 weeks of gestation, but thereafter requires specific experience and is not undertaken in many NHS settings. Although late-first-trimester abortion remains an extremely safe procedure, blood loss and other complications increase as gestation advances. It is important, therefore, to refer the woman for abortion promptly after the decision to terminate the pregnancy has been made.

Mid-trimester abortion

Second-trimester abortion accounts for 10–15% of all legal abortions in the UK. While many are done because of fetal malformation, it is often the women who are least able to cope with an unwanted pregnancy, particularly the very young, who first present at this time.

It is possible to induce abortion at this stage of pregnancy either medically or surgically. Surgical dilatation and evacuation (D&E) is the method of choice in the USA, but in the UK, its use is confined largely to gynaecologists in private practice. It may be necessary to dilate the cervix up to a diameter of 20 mm before the fetal parts can be extracted. D&E is a safe procedure in skilled hands, but if complications such as haemorrhage and perforation of the uterus are to be avoided, surgeons should be adequately trained. D&E should be preceded by cervical preparation, as described earlier.

Medical abortion for women presenting at greater than 15 weeks of gestation can be performed with mifepristone 600 or 200 mg orally, followed 36–48 h later by either gemeprost 1 mg vaginally every 3 h, up to a maximum of five pessaries, or by misoprostol 800 µg vaginally then 400 µg orally 3-hourly to a maximum of four oral doses.

Most women find the procedure painful and distressing, and require opiate analgesia. Evacuation of the uterus is necessary in approximately 30% of women who retain all or part of the placenta.

Abortion beyond 18 weeks of gestation is rare and is usually for pregnancies complicated by severe fetal malformation. Particularly distressing for both the mother and the staff, these late abortions are often effectively managed with vaginal prostaglandins in combination with mifepristone, with intra-amniotic urea or fetal intracardiac injection of potassium to minimize the chance of a live birth.

Follow-up

Anti-D immunoglobulin should be given to all non-sensitized Rhesus-D-negative women following any therapeutic abortion. Written advice about possible post-treatment symptoms, particularly those associated with infection, together with advice about what action to take should be given to patients before discharge home. All women should receive contraceptive advice and, if appropriate, supplies before going home. Ovulation can return within 20 days following abortion, and contraception should be started at the time of abortion if possible. All should be given a follow-up appointment within 2 weeks, either with the clinic which carried out the abortion or with a suitable alternative doctor. At follow-up, a pelvic examination should confirm complete abortion and the absence of infection. Discussion should include contraceptive advice and postabortion counselling, if required.

Complications

Mortality risk

In the UK, a woman is more likely to die in childbirth than she is to die from a complication of abortion (British Medical Association 2007). Although maternal mortality is, fortunately, extremely rare following abortion, the incidence of major complications, haemorrhage, thromboembolism, operative trauma (uterine perforation and cervical trauma) and infection is approximately 2%. The main factors affecting the incidence of complications in the RCGP study (Frank 1985) undertaken in the early 1980s were the place of operation (complications were less common when the abortion was done in a private hospital), gestation, method of abortion, sterilization at the time of operation and smoking habits.

Incomplete abortion

The most common complication following abortion is the persistence of placental and/or fetal tissue. Up to 5% of women undergoing first-trimester medical abortion will require surgical evacuation of the uterus within the first month. The incidence of incomplete abortion and ongoing pregnancy after vacuum aspiration rises as the gestation increases.

The occurrence of bleeding at 2 weeks after a medical or surgical abortion is not, in itself, an indication to evacuate the uterus. Ultrasound scans often show residual trophoblastic tissue even in women who have stopped bleeding. Although an ultrasound scan of the uterus and the measurement of human chorionic gonadotrophin in plasma may be helpful in diagnosing an ongoing pregnancy, the decision to evacuate the uterus should be made on clinical grounds (i.e. continued heavy or persistent bleeding from a bulky uterus in which the cervix is still dilated). The majority of women with an incomplete or missed abortion will pass the residual tissue with time if they are prepared to be patient. The belief that all women with an incomplete abortion had a high risk of intrauterine infection until the uterus was evacuated probably stemmed from the time when illegal abortion was common.

Minor complications

Some 10% of women undergoing abortion present to their general practitioner during the 3 weeks following the procedure with a variety of complaints related to the abortion. Lower abdominal pain, vaginal bleeding and passage of clots or trophoblastic tissue are relatively common and usually only require reassurance. It is, however, important to exclude infection. Established pelvic inflammatory disease with pyrexia, abdominal pain and offensive vaginal discharge occurs in approximately 1% of women whatever method of abortion is used.

Cervical and vaginal lacerations

Lacerations to the vagina and cervix are rare, and the risk of the latter can be reduced by pretreatment of the cervix in selected cases, as discussed earlier.

Late complications

There are very few late complications from abortion if women have been counselled carefully.

Psychological sequelae

Many women feel tearful and emotional for a few days following the abortion. However, many studies have demonstrated a significant improvement in psychological well-being by 3 months post abortion compared with before abortion (Adler et al 1990, 1992). Reviewers of existing literature have concluded that adverse psychiatric outcomes are observed in a minority of women following abortion, which are most often (although not exclusively) an exacerbation of morbidity predating the procedure, and that women denied abortion often experience significant ongoing resentment (Dagg 1991, Thorp et al 2002). Lack of a supportive partner, ambivalence regarding their decision or membership of a cultural group that forbids abortion are, unsurprisingly, risk factors for adverse psychological sequelae.

Infertility

Postabortion infection is a significant cause of tubal disease and infertility following illegal abortion. However, with modern methods performed under optimal conditions, the incidence of infection is very low, particularly where preoperative screening and treatment of infection are routine.

Subsequent pregnancy

Although damage to the cervix or perforation of the uterus can predispose to cervical incompetence, preterm delivery and/or uterine rupture, there is no significant increase in adverse outcome of any subsequent pregnancy.

KEY POINTS

1. Lack of contraceptive use continues to be a major problem in many developing countries.
2. The UKMEC, available in hard copy and online, provides consensus guidance on contraceptive prescribing.
3. The risks of MI and stroke in association with the COC have been exaggerated, and are minimal in women with no other risk factors, particularly smoking and hypertension.
4. The RR of VTE is increased in women taking the COC. However, the absolute risk of VTE is very small.
5. The CHC is associated with a highly significant reduction in the risk of ovarian and endometrial cancer, but those using the method for more than 8 years have an increased risk of having breast cancer diagnosed.
6. The efficacy of long-acting progestogen-only methods (implants, injectables, IUS) rivals that of sterilization.
7. The copper IUD is a very cheap and effective method of contraception which is underused.
8. The LNG-IUS reduces menstrual blood loss significantly and has increased the popularity of the IUD as a method of contraception.
9. EC is safe and is now available without prescription.
10. Antihormones, particularly antigestogens, show great promise for the development of new contraceptives.
11. There are a variety of ways of inducing therapeutic abortion, and women should be offered a choice of method within the context of a high-quality service which meets national standards.

Introduction

Human sexuality is important because it is inherent in everyone. It is an integral part of every human being and it is up to every individual to deal with their own sexuality in whichever way they choose. Although so fundamental to human existence, scientific documentation of sexuality is relatively recent. Historically, there was a persistent refusal to recognize that women could enjoy sex. In 1857, Acton stated that 'Happily for society the majority of women are not much troubled with sexual feelings of any kind'. At the beginning of the 20th Century, Havelock Ellis, an English doctor, gave scientific voice to the idea that sexual activity was important in its own right, not just as a means of procreation. He wrote that 'Reproduction... is not necessarily connected with sex, nor is sex necessarily concerned with reproduction'. Freud's revolutionary theories of psychoanalysis put sex and the subconscious firmly on the scientific agenda, but it was not until some decades later that Kinsey published his ground-breaking study on male and female sexual behaviour in 1948 and 1953. These reports led to uproar in their day and spearheaded the ever-increasing interest in human sexuality from the scientific viewpoint.

The Role of the Gynaecologist

The gynaecologist has a major role to play in the field of psychosexual problems, in both their prevention and detection. Gynaecology is the branch of medicine which focuses on a woman's sexual and reproductive system, which forms an essential essence of her femaleness and her perception of herself as a complete woman. Gynaecology is concerned with the area of the woman's body that is integrally involved in sexual activity. Sexual activity and emotions are closely linked, and it is therefore important to be aware of the effect

that any gynaecological problem may have on the woman's sexuality and, indeed, that of her partner, if she has one.

Modern medical teaching tends to recognize the emotional needs of patients, but unfortunately, some everyday gynaecological situations may unwittingly set the scene for psychosexual problems in the future. Psychosexual therapy concentrates on individual cases, interpreting each doctor-patient interaction as unique. Nonetheless, there are patterns of aetiologies which emerge in practice, such as a history of clinical procedures. Women may often trace their problem back to what may seem a minor gynaecological procedure, such as sterilization, termination of pregnancy or even vaginal examination, which is thus of crucial importance not only from a gynaecological perspective but also from a psychosexual perspective.

Human Sexuality

For ease of understanding, human sexuality can be divided into different components: gender identity, sexual orientation and sexual response.

Gender identity

Just under 50% of the population are diagnosed at birth as being female. They are biologically and legally female, and most tend to follow female biopsychosocial pathways throughout their lifetimes. Similarly, a male gender identity is experienced by the other 50% of the population, who are diagnosed at birth to be male. However, a tiny proportion of the population are transsexual. These are individuals whose biological sex and gender identity do not match. They are, in effect, born into the wrong body and may spend many difficult years undergoing a gender reassignment process. As all transsexuals are female at some stage

in their lives, they may come into contact with gynaecology services; therefore, it is important to have an awareness of this condition. A postoperative male-to-female transsexual presents on gynaecological examination as a hysterectomized female. The Gender Recognition Act 2004 allows change of birth certificate under UK law, and transwomen can now present to a gynaecologist without disclosing their trans status.

Sexual orientation

Sexual orientation is the definition of sexual attraction: the people to whom one's sexual desire is directed. Approximately 93% of the population are heterosexual (i.e. attracted to individuals of the opposite sex). Between 5% and 10% of the population are homosexual (i.e. men who are sexually attracted to men). A further 0.5–2% of women are lesbian (i.e. women who are sexually attracted to women). Seven percent of the population are bisexual and are attracted to both men and women. In the UK National Survey of Sexual Attitudes and Lifestyles, over half of the men who had had a male sexual partner in the previous 5 years had also had a female partner; the figure was higher for females at 75.8% (Wellins et al 1994).

Sexual orientation has particular relevance in well-woman health care. Lesbians may be reluctant to discuss their sexual orientation with a clinician, but as the majority have experienced heterosexual sexual intercourse or had vaginal penetrative sexual activity with fingers or sex toys, they are at risk of cervical dysplasia and sexually transmitted infection. Lesbians should be included in national cervical screening programmes and have the same well-woman checks as the rest of the female population. Lesbians generally have positive attitudes to the new human papilloma virus vaccine programmes, but feel that any health promotion materials should recognize their sexual orientation (McNair et al 2009) in order to increase uptake (see Chapter 66, Lesbian health issues, for more information).

Bisexual women are at the highest risk of sexual morbidity, and may be reluctant to speak openly about their sexuality to clinicians.

Sexual response

The human physiological sexual response is dependent not only on intact endocrine, vascular and neurological input, but also on sensory input. This has been described as the 'psychosomatic circle of sex' (Bancroft 2008). Female sexual responsiveness is a result of sensory input through the peripheral nerves of the somatic and autonomic nervous system, as well as through the cranial nerves and psychogenic stimulation. Precisely where and how afferent information is processed within the spinal cord and brain is unknown (Yang 2000). The frontal and temporal lobes and anterior hypothalamus are all shown to have some function in mediating the sexual response, but the extent of this is still unclear. Genital motor responses include pelvic vasocongestion and vaginal lubrication. During sexual intercourse, the vagina lengthens, the labia increase in size, the uterus draws back and the clitoris retracts; at orgasm, there is also contraction of the uterine and pelvic muscles.

Clinical clarification of the human sexual response was based on the Masters and Johnson model of four phases: excitement, plateau, orgasm and resolution. This description was then modified by Kaplan to a triphasic model of desire, arousal and orgasm. These concepts provide the working models on which behavioural therapies for sexual problems are based. Recent scientific arguments have proposed that sexual desire is, in fact, the first early stage of arousal, triggered by a stimulus which has sexual meaning and is modified by situational and partner variables (Janssen et al 2000).

Most human sexuality is non-problematic and will not be within the domain of the clinician. It is only when something goes wrong with the patient's sexual response that they may seek professional help.

Sexual Problems in General

Population prevalence

The majority of the population at any one time have a trouble-free sex life. There is, however, a substantial minority for whom dealing with and expressing their sexuality is problematic. These problems may only be temporary or situational. If they persist and become increasingly distressing, the individual may seek professional help. The population prevalence of some degree of sexual dysfunction is estimated to be approximately 20%. Prevalence increases with age; overall, 40–45% of women and 20–30% of adult men report at least one sexual dysfunction at any one time (Lewis et al 2004). In the National Health and Social Life Survey (Laumann et al 1999), one-third of women reported loss of libido. Almost 25% did not experience orgasm. Approximately 20% had problems with vaginal lubrication, and a similar number did not enjoy sex. This study suggested that there was a substantial comorbidity of sexual problems. A study of US women (West et al 2008) showed that whilst 26.7% of premenopausal women had low sexual desire, 52.4% of naturally menopausal women had the same complaint. For males, the prevalence of some degree of erectile dysfunction has been reported as 30% of all males between the ages of 40 and 70 years. Premature ejaculation occurs in 10–30% of men during their lifetime. In a control group of 591 members of the general population in a Dutch study, 8.7% of men and 14.9% of women reported a sexual dysfunction unrelated to age (Diemont et al 2000), which is lower than that reported in other countries.

Definitions of Sexual Dysfunction

In the recent literature, there has been much positive debate about redefining sexual disorders, especially in the female. It is generally agreed that the definitions need clarification, especially in relation to research (Derogatis and Burnett 2008). Clinically, there is a lot of overlap in presentation, and clearer definition would help preventive and treatment strategies. Much work has concentrated on female sexual dysfunction, helping in understanding the organic basis for some problems (Meston and Bradford 2007); however, massive treatment breakthroughs have yet to follow.

Having a sexual dysfunction does not necessarily mean that the individual has a sexual problem. This will depend on the effect, if any, that the dysfunction has on the life of the individual in terms of their feelings, relationships and lifestyle. Conversely, restoration of sexual function may not solve the sexual problem; in fact, it may serve to highlight an underlying emotional or relationship discord. Individuals with psychosexual problems usually have no organic sexual dysfunction whatsoever.

Problems of function or desire

Sexual disorders can be divided into problems of function or desire. They are often interlinked. For example, impaired sexual function, such as some degree of erectile problem, can result in the man protecting himself from the distress of failure by emotionally shutting himself off from coitus altogether. This results in loss of libido. If a woman is experiencing loss of function such as dyspareunia, she may subconsciously employ the same defensive mechanisms, and loss of desire develops.

The most common female sexual problems are vaginismus, loss of libido, dyspareunia and inorgasmia. There will be differences in the frequency of presenting sexual complaints in different clinical settings. An American gynaecology clinic sample showed loss of libido (87.2%) with inorgasmia (83%) and dyspareunia (72%) (Nusbaum et al 2000). In a community-based setting such as a family planning clinic, however, loss of libido, dyspareunia and vaginismus are the most common presenting complaints, with a low incidence of inorgasmia.

In males, erectile dysfunction, ejaculatory disorders and loss of libido are the most frequent presenting complaints, all of which will affect the partner to some degree.

Problems relevant to gynaecology

There are many gynaecological conditions which may predispose to sexual problems. Any disease or its treatment which results in alteration of the genitalia may cause functional sexual difficulties. These conditions may range from having colposcopy, where spontaneous interest in sex was found to be lower 6 months post procedure, irrespective of whether or not treatment was needed (Hellsten 2008), to traumatic obstetric delivery or gynaecological malignancy. Trauma or disease, however, may cause an alteration in the woman's perception of herself, such as distorted body image causing sexual problems. This may or may not be directly related to physical reality. An exceptionally high rate of sexual dissatisfaction was found in a gynaecology clinic sample in the USA. Over 98.8% of the sample reported one or more sexual worries, and body image concerns were reported by 68.5% of the 1480 women who attended (Nusbaum et al 2000). A study of Dutch gynaecologists found that one in 14 of their patients presenting in the previous week had problems of a sexual nature, mainly dyspareunia or lack of sexual desire (Frenken and van Tol 1987). A significant degree of deterioration of sexual function was described in a study of 41 women who had undergone vulvectomy, attributed to disturbed body image rather than physical impairment (Green et al 2000). The rate of sexual problems in women with gynaecological

cancers is approximately 50%. The main complaint of this client group is lack of opportunity to discuss these problems.

Once any gynaecological treatment is completed, the treatment approach for the sexual problem is the same as for any other patient.

Sexual Problems in the Female

Vaginismus

Vaginismus is a condition in which nothing is able to enter the vagina. This means that penetrative sexual intercourse does not take place. It is caused by psychogenically mediated involuntary spasm of the vaginal muscles. Vaginismus can be primary or secondary. In primary vaginismus, nothing has ever entered the woman's vagina. A useful diagnostic question is 'Have you ever used a tampon'. In a case of primary vaginismus, the answer will always be 'no'. Secondary vaginismus can appear at any time in a woman's life, sometimes after childbirth or any other life-changing event.

The vagina is physiologically intact in a case of vaginismus. There is no stenosis or organic disorder. This is a psychogenic condition for which the treatment is psychosexual, never surgical.

Presentation

Vaginismus is a condition which usually has a masked presentation. One of the most common presentations is the avoidance of cervical smears. No woman likes having a vaginal examination or smear. The alert clinician, however, will observe a patient's persistent avoidance of examination or a fear of being examined which is in excess of that usually observed by the clinician. If vaginismus is suspected, a forced vaginal examination should not be done. This is the equivalent of medical rape, which can have a long-lasting traumatic effect on the woman.

Vaginismus can present initially as dyspareunia or painful sexual intercourse. In this case, the couple are not really having sex; as the erect penis attempts vaginal entry, the vaginal muscles contract and the interaction becomes painful. Vaginismus can also be a cofactor in loss of libido, although more commonly the woman has a strong desire to have sex, 'just like everybody else'.

Vaginismus may present as infertility. It is essential to ask the infertile couple whether or not they are having vaginal intercourse. Patients still reach tertiary referral centres for assisted conception where it is discovered that sexual intercourse has never taken place and vaginismus is the primary diagnosis.

Unconsummated relationships are usually due to vaginismus, but can occasionally be due to male sexual dysfunction.

Treatment

There are various different approaches to the treatment of vaginismus. There are no data to suggest which method is best, and to date there has been no randomized controlled trial comparing methods of treatment. Treated by a skilled clinician, the reported cure rate is 90%.

Psychodynamic methods

The trained clinician helps the patient to understand the basis for her problem and to recognize the barriers to sex. This method can take up to 2 years to cure the vaginismus, but deals with the root causes of the problem as well as offering practical solutions.

Behavioural methods

Evidence shows that cognitive behavioural therapy is effective (van Lankveld 2006), and can also be used with couples (Kabakci and Batur 2003). A useful adjunct to therapy is the use of vaginal trainers, which are plastic 'pseudopenises' made in graduated sizes, which the woman is taught to insert into her own vagina. The same effect can be gained by using fingers. This teaches her that she can be in control of what enters her body. This can be a good adjunct to psychodynamic therapy.

Supplying vaginal trainers without supportive therapy is unlikely to show sustained benefit.

Classic couple therapy, based on the Masters and Johnson model, is also shown to be effective, with success rates of 93% reported (Jeng 2006). Recent reports of the intravaginal use of botulinum toxin are promising (Ghazizadeh and Nikzad 2004). The use of surrogate male partners was shown to be effective in women without a cooperative partner (Ben-Zion 2007), but clearly raises many social and ethical issues in treatment.

Surgery has no place in the treatment of vaginismus.

Inorgasmia

Inorgasmia is the lack of ability to experience orgasm. There are two main areas of innervation in the female genital region that can produce orgasmic symptoms if stimulated. The main area is the clitoris and there is another inside the vagina, about two-thirds of the way up, close to the urethra. This is known as the 'G-spot'.

Presentation

The woman will either complain of inability to experience orgasm or may say that she does not know whether or not the feelings she is having constitute orgasm. Presentation at a clinic with this complaint will usually have been prompted by the acquisition of a new partner, the inability to find a partner or by popular media interest in the topic.

Treatment

There are some women who have no feelings at all in the clitoral area. Women with selective serotonin reuptake inhibitor (SSRI)-induced loss of sensation and sexual dysfunction showed improvement on taking sildenafil (Nurnberg et al 2008). Combined oestrogen and androgen therapy may improve sexual sensation in menopausally triggered inorgasmia. Sildenafil may also improve clitoral blood flow in menopausal women with orgasmic dysfunction and women with type 1 diabetes.

With women who have never experienced orgasm, however, drug treatment alone is unlikely to work. Encouraging body self-awareness, by discussion of female genital anatomy and physiology, will help. Encouraging masturba-

tion is very rewarding. If this is combined with psychodynamic input, the patient usually responds.

Loss of libido

Loss of libido is loss of sexual desire. It is generally associated with loss of self-esteem due to a multitude of underlying causes. There may be a traumatic event in the past which has not been dealt with emotionally and which may cause problems, such as loss of libido, at a later stage in the woman's lifetime. Examples of this are rape, sexual or emotional abuse, or a loss such as bereavement or redundancy leading to loss of status and loss of self-esteem.

There are associations between loss of desire and hormonal status in postmenopausal women. Hypoactive sexual desire disorder is much more common in menopausal women, especially young women with surgical menopause. There is, however, no physiological marker for loss of libido, and there is rarely a 'quick fix' solution to the problem.

Presentation

Loss of libido may present as depression or as a relationship problem. The woman may be uncomfortable broaching the subject but, if prompted by an empathetic clinician, may disclose the problem. In areas of gynaecological health care where body image becomes problematic, such as oncology, menopause and continence, loss of libido may be an overlooked complaint.

Treatment

The core treatment for loss of libido is psychosexual therapy, which deals with the underlying psychogenic origin of the problem. Counselling before procedures can allow women to explore their feelings in relation to these procedures. A past history of abortion is not uncommon in women with loss of libido. Pretermination of pregnancy counselling is, of necessity, information based and time limited. After termination of pregnancy, however, there is an opportunity for the woman to come to terms with what has happened, thus preventing the development of sexual problems later in life and hopefully preventing repeat unwanted pregnancy. After sterilization, there will be some women who suffer loss of libido. Even if they have no regrets over the procedure, they may not have realized the emotional impact of losing their fertility as they have not understood the difference between choosing not to have a child and not being able to conceive.

In cases where the loss of libido can be clearly linked to a hormonal trigger, such as starting a different combined oral contraceptive, changing contraception can improve the problem.

There is some evidence for the addition of androgens to oestrogen replacement therapy for menopausal loss of libido (Kingsberg 2007). Hormonal therapy alone, however, can only return a woman to her premenopausal status and cannot change any underlying emotional blocks to sexual desire. The menopause is a time of major social and emotional upheaval for many women, which can be as overwhelming as adolescence, so psychosexual therapy combined with appropriate hormone replacement therapy would seem to be best practice.

Dyspareunia

Dyspareunia is painful sexual intercourse. It may be described as deep or superficial. There are organic causes for this, such as post delivery, after gynaecological operations, genital infections and in any condition which causes vaginal dryness, such as menopause. Vulval pain syndrome, or vulvodynia, is a complex condition which causes severe dyspareunia.

Vaginal dryness can be physiological, caused by lack of sufficient sexual stimulation during intercourse.

Presentation

Dyspareunia is a common presenting complaint to the gynaecologist. Some women (and doctors!) find it easier to discuss than some other sexual problems, as it seems more likely than other sexual complaints to have an organic origin. Postdelivery dyspareunia is reported frequently but, on average, women resume sexual intercourse at 7 weeks post partum (Byrd et al 1998). Approximately 15% of women have chronic dyspareunia of unclear origin (Weijmar Schultz et al 2005), and as well as causing distress to the patient, this presents an enormous challenge to the gynaecologist.

Treatment

If dyspareunia persists despite clinical evidence of cure of the underlying condition, or no clinical findings despite full appropriate genitourinary and gynaecological investigation, psychosexual therapy should be considered. Recommended therapy for vulval pain syndromes is multidisciplinary with psychosexual input in coordination with gynaecological treatment (Nunns 2000). There is now a recognition that more research and clarification of definitions of sexual pain, particularly in relation to vulvar vestibulitis and vaginismus, is required in order to focus treatment (Weijmar Schultz et al 2005).

Various treatments now have evidence to recommend their use. Pelvic floor physiotherapy is an important tool of modern assessment and treatment (Rosenbaum 2005). The use of vibrators (Zolnoun et al 2008) is helpful and can be easily accessed and used by the women without clinical intervention. Hypnosis (Pukall et al 2007) and vaginal botulinum toxin type A have been reported as having positive therapeutic effects, and can increase the ability to have relatively pain-free and pleasurable sexual intercourse.

The emotional aspects of vulvar pain should never be ignored. Sometimes the memory of a previous painful condition may lead to expectation of pain on intercourse. This can produce involuntary vaginal muscle spasm, causing secondary vaginismus and thereby perpetuating the dyspareunia despite treatment of the original cause.

Physiological dyspareunia is caused by vaginal dryness due to lack of sufficient and appropriate sexual stimulation. It is treated by helping the woman to understand the cause of the problem. Discussion of sexual technique may help, emphasizing foreplay. Enabling the woman to gain insight into the nature of her relationship with her partner is an essential part of this process.

Sexual problems of lesbians

Gynaecologists should remember that not all women are heterosexual. Lesbians have similar sexual problems to other women but, as they find it difficult to disclose their sexual orientation to doctors, it may be even harder for them to discuss sexual problems than it is for heterosexuals. Women complaining of loss of libido, inorgasmia or dyspareunia may be in same-sex relationships. Vaginal penetration, as with all women, may occur with fingers and sex toys. Once organic causes have been excluded, psychosexual therapy should be offered. Synchronicity of menstruation in women living together, possibly due to pheromonal influence, has been documented (McClintock 1998). This is not universal but, where it exists, the coincidence of severe premenstrual symptoms can trigger domestic violence in lesbian couples, which can be an underlying cause of sexual problems (see Chapter 66, Lesbian health issues, for more information).

Sexual Problems in the Male

Gynaecologists are unlikely to be in the front line when dealing with male sexual problems, but as many of their female patients have male partners, it is important to have an overview of this area. If her partner has sexual problems, the woman can feel hurt and rejected, and will frequently blame herself, presenting at a clinic for help in solving the problem.

Erectile dysfunction

Erectile dysfunction is the inability to sustain a penile erection sufficient to achieve satisfactory penetrative sexual intercourse. According to the oft-quoted Massachusetts Male Aging Study, the incidence of erectile dysfunction in men aged 40–69 years is 25.9 cases per 1000 man-years; 60% of cases are organic in origin, 15% are psychogenic and 25% are of mixed origin (Aytac et al 2000).

Aetiology

Erectile dysfunction can be caused by any disruption of the neurological, endocrine or vascular supply to the genitalia. It can also occur for entirely psychogenic reasons. Associated factors are age, diabetes, alcohol intake, hypertension and the side-effects of many medications. Erectile dysfunction reduces quality of life and may lead to other associated sexual problems, such as loss of libido.

Presentation

The man with erectile dysfunction may present to a doctor himself, although it is not unusual for the female partner of a male with a sexual problem to present herself as the patient. She may say that she is experiencing either loss of sexual interest or painful sex. The couple themselves may not recognize where the problem lies.

Treatment

The treatment depends on the cause and falls into four basic categories: chemical, mechanical, surgical and psychosexual.

Oral therapy is now available which has revolutionized treatment of this distressing condition. The phosphodiesterase type 5, cyclic GMP inhibitors are now widely used worldwide. The drugs are facilitators, not initiators, of erections. These oral medications have reported efficacy rates of approximately 70% for sexual intercourse. They produce a vasodilatory effect and must not be used routinely for patients with coronary insufficiency on nitrates. The recreational use of amyl nitrate 'poppers', employed to facilitate anal intercourse, is strongly contraindicated with these drugs.

Locally acting chemical treatments can also be used. Alprostadil, which is prostaglandin E, can be injected into the base of the penis, causing smooth muscle relaxation and resulting in an erection. It can also be introduced by a tiny pellet into the urethra, causing an erection. Both methods have success rates of approximately 70%. Success rates with this urethral medication have been improved by the use of a penile constriction band which augments local retention. A newer combination of alprostadil and an α -adrenergic antagonist enhances erection rates, and other medications are being researched. This causes smooth muscle relaxation, leading to engorgement of the corpora cavernosa and erection of the penis. Although there can be some local discomfort, there are few contraindications to this therapy. It does, however, require manual dexterity and a willingness to inject or to insert medication into the penis. Unsurprisingly, there are fairly high discontinuation rates for this type of invasive therapy.

The simplest, non-invasive treatments are vacuum devices. A constriction ring is first applied to the base of the flaccid penis, then a vacuum is created, causing engorgement of the corpora cavernosa which is maintained by the constriction ring. This method creates a slightly blue, cold erection which may be sufficient for intercourse, and which is suitable for some men who prefer non-chemical treatment methods. Surgery is required if a venous shunt has been demonstrated or to insert a prosthesis, if there are no other options for treatment.

Psychosexual therapy is an important therapy to consider in cases of erectile dysfunction, either on its own or as an adjunct to physical therapy, as 40% of cases of erectile dysfunction have a psychogenic element. This form of treatment allows the man to explore all the issues surrounding his problem, and also allows him to include his partner in treatment if he wishes. It also takes a whole-person approach, rather than merely focusing on the genitalia.

Premature ejaculation

Premature ejaculation is the most common male sexual problem worldwide. It is a condition where the male reaches the point of orgasm and ejaculates very rapidly, before satisfactory sexual intercourse has taken place. It is frequently a complaint of young men but may present in all age groups.

Presentation

The man suffering from premature ejaculation will ask for clinical help if it is affecting his sexual satisfaction or relationships.

Treatment

A psychodynamic approach will help the man to understand and cope with his anxieties related to the problem.

The 'squeeze' technique can be used. If the thumb and forefinger are used to squeeze firmly at the base of the glans penis at the point of ejaculation, ejaculation will be delayed. This technique, however, requires a good degree of coordination.

The mainstay of treatment, however, is the use of anti-depressant medication, such as clomipramine or SSRIs, which have been shown to increase ejaculation latency. Daily use of SSRIs is more effective than on-demand treatment (Waldinger 2007).

Delayed ejaculation

Delayed ejaculation is a condition which is usually psychogenic in origin. Infrequently, it can be a side-effect of some medications. It can be extremely distressing to the female partner, and if penetrative, thrusting sexual intercourse becomes prolonged due to a failure of the man to become orgasmic, it can lead to dyspareunia. The male may be able to ejaculate when masturbating but is unable to do so intravaginally. This could be for various subconscious reasons, some of which are fear of losing control, fear of causing pregnancy or unwillingness to make a commitment to his partner (Thexton 1992).

Treatment

Psychosexual therapy is the treatment of choice. This problem may take a prolonged course of therapy before positive outcomes are achieved.

Loss of libido

This can affect men as well as women. Rarely, lack of testosterone may be implicated but the cause is usually emotional and will frequently be linked to some cause of loss of self-esteem in the man.

Treatments

Most problems of a sexual nature have a psychogenic origin. Even sexual problems with clear organic origins tend to have some degree of psychogenic overlay, as sexual activity, or the lack of it, has emotional impacts.

There are three main treatment modalities for sexual problems: psychodynamic methods, behavioural methods and drug treatments.

Psychodynamic methods

Psychodynamic medicine is concerned with understanding how emotional factors interfere with sexual activity and enjoyment. These emotional factors may not be at the conscious level. The aim of treatment is to enable the patient to resolve the problem by removing the psychological blocks to satisfactory sexual activity and relationships (Skrine 1989). This is achieved by taking a 'mind-body' approach to the patient and their sexual problem. The psychosexually trained clinician will explore the problem with the patient

by interpreting the doctor–patient interaction, and feeding these observations back to the patient in order to elicit their response.

An important part of this treatment is the psychogenic genital examination. Many of the patient's underlying attitudes, fears and fantasies related to their sexual problem may be revealed in relation to this part of the consultation.

The philosophy of treatment is that the patient is 'whoever presents' at the consultation. This mode of treatment is suitable for individuals, regardless of whether or not they are in a relationship. It is also appropriate for couples, regardless of gender identity or sexual orientation.

Not all psychosexual problems require prolonged specialist treatment. A single consultation with a suitably trained doctor is sufficient help for some patients.

Behavioural methods

Behavioural methods involve a more didactic, 'hands-on' approach to treatment. This philosophy of treatment was developed through the early work of Masters and Johnson, and Helen Singer Kaplan. Patients are given practical tasks in order to learn or relearn how to experience and enjoy sexual activity. This approach maintains that the many causes of sexual dysfunction can be treated effectively by a programme combining education, homework assignments and counselling. A staged approach to re-establishing healthy sexual contact can be a useful therapeutic tool when dealing with couples, and has been modified to treat single individuals although it is felt to be of most use for people with partners.

Cognitive behavioural therapy is increasingly used as a practical and effective method of treatment of sexual problems.

Drug treatments

Drug treatment of male erectile dysfunction has been shown to have a high success rate, and there is some evidence for improvements in premature ejaculation with antidepressants (e.g. SSRIs) or anticholinergics (e.g. clomipramine). Medication may restore genital function, but associated emotional and relationship issues should also be addressed appropriately.

For women, there has been increased interest in the possibility of drug treatment for sexual dysfunction. Despite much research, the only evidence-based conclusion is that appropriate hormone replacement therapy with the addition of androgen will improve sexual functioning in some post-menopausal women. Research has shown an influence of adrenergic compounds on physiological sexual arousal, but not on the woman's subjective sexual experience (Everaerd and Laan 2000), which is, in fact, what matters most in

sexual functioning. Compounds used to increase male penile blood flow have been shown to have limited success in women in clearly defined circumstances. If the woman's medication is thought to be causally associated with loss of libido, such as some hormonal contraceptives, antiepileptics and psychotropic drugs, a change of drug may help.

The mainstay of treatment for sexual problems, however, particularly for women, is therapy which deals with the emotional and interpersonal blocks to satisfactory sexual activity. Sensitivity to the emotional aspects of the consultation, and possible sexual sequelae of the gynaecological condition or its treatment, may prevent the onset of sexual problems in the future.

Service provision

Over the last few years, the amount of research into all aspects of women's sexual problems has proliferated. Sadly, service provision and professional training do not seem to have kept up the same pace. Many localities have some provision of service for the treatment of psychosexual problems; however, rural and outlying areas often have none. Sexual and reproductive healthcare services may have an attached sexual problems clinic, which provides treatment in a non-threatening and non-judgemental, community-based environment. In areas of gynaecological care, such as cancer services, where the prevalence of sexual problems can be as high as 50%, the provision of sexual problems services is not uniformly available, despite women's wishes for the provision of these services.

Many people find it very embarrassing to disclose a sexual problem to anyone, and a self-referral facility for making appointments can encourage patients to come forward for treatment.

Conclusion

With such a large minority of women experiencing some form of sexual difficulty in their lifetime, from adolescence to menopause and beyond, it is vital for the gynaecologist to be aware of these conditions and to allow the woman to voice her concerns in a confidential, empathetic and non-threatening environment. Just being listened to and having her concerns acknowledged in an empathetic and non-judgemental manner can be enough to initiate the therapeutic process. If she wishes, referral can be made to the appropriate local sexual problems service. With suitable training, however, it is possible to employ brief focused analytical techniques within the context of a routine gynaecological appointment. This allows the gynaecologist to assess the psychosexual element of the situation, and enhances the quality of care for the patient.

KEY POINTS

1. Sexual problems are prevalent in society and have either an organic, emotional or mixed origin. The mode of treatment depends on the cause.
2. Sexual problems can present unexpectedly in any clinical setting, and commonly in community or hospital gynaecology clinics.
3. Patients find it difficult to disclose problems of a sexual nature. Increased awareness by the gynaecologist and a willingness to introduce the topic is helpful.
4. A gynaecologist trained in basic psychosexual techniques can provide help to the patient within the context of the gynaecology clinic setting.

5. Dyspareunia presenting to the gynaecologist with negative clinical findings may have a psychogenic origin.
6. Primary vaginismus is of psychogenic origin and surgery has no place in its treatment.
7. Loss of libido is mostly of emotional origin, but the addition of testosterone to hormone replacement therapy is beneficial in some menopausal women.

Introduction

Menstrual abnormality is a common reason why women present at gynaecological outpatient clinics, and heavy menstrual bleeding (HMB) is one of the most common causes of iron-deficiency anaemia in Western women (Cohen and Gibor 1980). The average woman now experiences approximately 400 cycles, in contrast to the 40 or so she would have experienced 50 years ago. This is mainly due to smaller family size, availability of effective contraception, occurrence of an earlier menarche and later onset of menopause (Higham 1994). In addition to having an increased number of cycles, a significant number of women now work outside home, where disruption of work due to episodes of flooding is even less tolerable. Consequently, disorders of menstruation have become a significant public health issue.

Menstruation

At the end of the ovarian cycle, a major portion of the endometrium in primates undergoes periodic necrosis and sloughing associated with blood loss. Hence, the endometrium is a site of recurrent physiological injury and repair (Critchley et al 2001). During menstruation, the gonadal steroids reach their lowest levels. The nature of the supportive effect on the endometrium is unknown, although possible mechanisms will be discussed later.

Anatomy of the uterus

The uterus is a muscular, pear-shaped organ consisting of a fundus, body and cervix. The uterus receives the fallopian

tubes at the cornua, whilst the cervix protrudes and opens into the vaginal vault.

The wall of the uterus consists of three layers: the serous coat, the myometrium and the endometrium. The serous coat is firmly adherent to the myometrium, which consists of smooth muscle fibres, the main branches of the blood vessels, and the nerves of the uterus and connective tissue. The endometrium consists principally of glandular and stromal cells, although its structure does vary spatially within the uterus and temporally with the stage of the menstrual cycle. The human endometrium is a dynamic tissue that, in response to the prevailing steroid environment of sequential oestrogen and progesterone exposure, undergoes well-characterized cycles of proliferation, differentiation and tissue breakdown on a monthly basis (Jabbour et al 2006).

Blood supply of the uterus

The blood supply of the uterus (Figure 31.1) is via the uterine artery, a branch of the anterior division of the internal iliac artery. It passes medially across the pelvic floor above the ureter, reaching the uterus at the supravaginal part of the cervix. Giving a branch to the cervix and vagina, the vessel turns upwards between the leaves of the broad ligament to run alongside the uterus as far as the entrance of the fallopian tube, where it anastomoses with the tubal branch of the ovarian artery. In its course, it gives off branches that penetrate the walls of the uterus. Within the myometrium, the uterine and ovarian arteries form the arcuate arteries. These, in turn, give rise to the radial arteries which, after passing through the endometrial-myometrial junction, branch into the basal arterioles, supplying the basal endometrium, and

Figure 31.1 Schematic representation of the blood supply of the uterus.

the spiral arterioles, supplying the superficial layer of the endometrium. Spiral arterioles are end arterioles and are only present in species that menstruate. Each supplies an area of 4–9 mm². Branching of the spiral arterioles occurs throughout the superficial layer of the endometrium. Just below the surface epithelium, they break up into a prominent subepithelial plexus that drains into venous sinuses.

The endometrial vasculature is unlike any other vascular bed owing to its cyclic remodelling and regression during the menstrual cycle. These vessels are sensitive to changes in gonadal steroid levels, and at menstruation, the capillaries are shed with the glands and stroma (Rogers et al 1998). A recent study confirmed that crucial structural components in the endometrium during the menstrual process are the component blood vessels and the dynamic population of leukocytes that influx at this time (Jabbour et al 2006).

Histology of the uterus

The endometrium

The endometrium is composed of heterogeneous cell types that undergo cyclic synchronized waves of proliferation and differentiation in response to the rise and fall of oestrogen and progesterone. Histologically, it is divided into a superficial or functional layer, which lies adjacent to the uterine cavity, and a basalis, or deeper layer.

In the uterus, the superficial endometrial layer is characterized by rapid proliferation during the follicular phase of the cycle, followed by secretory transformation of the glandular epithelium, predecidualization of the stromal compartment and influx of uterine natural killer cells in the luteal phase of the cycle (King et al 1998).

During the proliferative phase, the short, straight epithelial glands elongate and become tortuous (Figure 31.2A). Changes occur in the position of the nuclei and the number

of mitoses. During the secretory phase, the glands increase in diameter and tortuosity, and vacuoles appear in the cellular cytoplasm (Figure 31.2B). The tissue also becomes markedly oedematous.

These morphological events are controlled by highly coordinated activation of certain gene sets essential for the regulation of uterine function. For instance, after ovulation, the sequential expression of progesterone-dependent genes defines a limited period of uterine receptivity or, in the absence of pregnancy, maintains vascular integrity prior to menstruation (Tabibzadeh and Babaknia 1995, Lockwood et al 1998). In addition, recent application of knowledge from the human genome, utilizing microarray technologies, has allowed several groups to contribute to a rapidly expanding literature on gene profiles during the 'putative window' of implantation (Carson et al 2002, Kao et al 2002, Riesewijk et al 2003).

In contrast, the basal endometrium shows no 'classic' sex steroid hormone response and is characterized by low proliferative activity, absence of glandular secretory transformation and lack of a predecidualization reaction in the late luteal phase. This absence of the 'classic' sex steroid hormone response does not, however, imply refractoriness to ovarian hormones. The basal layer is an important source of uterotonicins and the site of active metaplasia of basal endometrial stromal cells into myofibroblasts and vice versa. It is further characterized by the presence of resident CD-3-positive T-lymphocyte aggregates.

The microvascular blood supply of the endometrium undergoes the unique process of benign angiogenesis, and is under the control of ovarian steroids during reproductive life. Following cessation of menstruation, they are simple in form, extending just into the endometrium. The secretory phase is characterized by the growth of arterioles. In the late secretory phase, coiling occurs due to proliferation and extension of the arterioles (Figure 31.2C). With the fall in steroid concentrations, menstrual shedding of the functional layer of the endometrium occurs (Figure 31.2D). Dramatic changes occur in the spiral arterioles at menstruation. These changes were described by Markee (1948) after experiments involving the transplantation of endometrium into the anterior chamber of the eye of the Rhesus monkey. This work was the cornerstone of current concepts of menstruation. On observing the bleeding process, Markee suggested that the arteriolar coiling caused constriction of the vessel lumen with vascular stasis and leukocytic infiltration. Approximately 24 h premenstrually, intense vasoconstriction led to ischaemic damage, followed by vasodilatation with haemorrhage from both arterial and venous vessels: 75% of the loss was arteriolar, 15% was venous and 10% was diapedesis of erythrocytes (Markee 1940).

The myometrium

The human myometrium is structurally and functionally polarized during the reproductive years. Compared with the outer myometrium, the subendometrial layer or junctional zone (JZ) is characterized by higher cell density, lower cellular nuclear:cytoplasmic ratios and the expression of different extracellular matrix (ECM) components (Brosens et al 1998, Campbell et al 1998). Additionally, evidence from ³¹P nuclear magnetic resonance spectroscopic studies has dem-

Figure 31.2 (A) Proliferative endometrium showing tubular glands. Mitoses are present in glands and stroma ($\times 10$). (B) Early secretory endometrium showing subnuclear vacuolation (v) and the presence of secretions. There are now few mitoses ($\times 40$). (C) Midsecretory endometrium (day 23) characterized by 'saw-toothed' glands (g), convoluted spiral arterioles (sa) and stromal oedema (o) ($\times 40$). (D) Menstruating endometrium. The glands (g) are now thin and show little secretory activity. There are lakes of haemorrhage (h) and the endometrium is beginning to break up (*). There is infiltration with white blood cells ($\times 10$). (E) Cystic glandular hyperplasia ($\times 4$).

onstrated biochemical heterogeneity between both myometrial layers (Xu et al 1997).

The differentiation of the myometrium into two distinct layers is strictly under ovarian hormonal control. In premenarchal girls and postmenopausal women, the zonal anatomy is often indistinct. Ovarian suppression with gonadotrophin-releasing hormone (GnRH) analogues leads to a magnetic resonance imaging (MRI) appearance of the uterus mimicking that of postmenopausal women, whilst hormone replacement therapy in postmenopausal women results in the reappearance of myometrial zonal anatomy (Demas et al 1985).

Further evidence for hormone responsiveness of the JZ is provided by the work of Wiczysk et al (1988), who demonstrated changes in JZ thickness throughout the menstrual cycle in conjunction with endometrial thickness.

Mechanisms of Normal Menstruation and Control of Blood Loss

The tissue components of the endometrium are a surface epithelium and associated glands, with a connective tissue stroma in which an elaborate vascular tree is embedded. The endometrial surface area is large ($10\text{--}45\text{ cm}^2$), indicating that haemostasis during menstruation is usually very efficient.

Withdrawal of progesterone from an oestrogen-primed endometrium results in menstrual shedding. Shedding arises because of the induction of matrix metalloproteinases (MMPs) from the endometrium, in particular MMPs 1, 2 and 9 (Jeziorska et al 1996, Marbaix et al 1996). This arises through a mechanism of upregulation of transforming

growth factor-beta (TGF- β) (Bruner et al 1995). The blood vessels are thus denuded of their support. Spiral arterioles and venules are cleaved at the level of the JZ between the endometrial functionalis and basalis, with subsequent bleeding.

Factors involved in the control of menstrual blood loss are:

- haemostasis;
- vasoconstriction; and
- endometrial repair.

Derangement of any of these mechanisms is likely to lead to excessive menstrual loss.

Haemostasis

Coagulation occurs in the distal endometrium, and platelets found within the endometrial cavity are deactivated and do not respond to collagen, as they would elsewhere. Once clinical bleeding and tissue shedding have started, haemostatic plug formation occurs, but less rapidly and less completely than is observed in human skin wounds (Christiaens et al 1982). Certain haemorrhagic conditions (e.g. thrombocytopenic purpura) are associated with increased incidence of HMB, suggesting that abnormalities of platelet structure may be important.

The coagulation cascade operates in the uterus and endometrium as in other tissues. Platelet accumulation, platelet degranulation and fibrin deposition occur within hours of the onset of menstruation, sealing endometrial vessels. The platelet count in menstrual discharge is only one-tenth of that seen in peripheral blood. This is probably due to the consumption of platelet aggregates in endometrial blood vessels early in the haemostatic processes of menstruation (de Merre et al 1967). Additionally, these platelets have been found to be devoid of granules, and they fail to aggregate when challenged with aggregating stimuli such as adenosine diphosphate and collagen. Compared with peripheral blood platelets, those in menstrual fluid do not produce appreciable cyclo-oxygenase products from arachidonic acid (Christiaens et al 1981, Sheppard et al 1983, Rees et al 1984).

Since prevention of clot formation is necessary to deter scarring and obliteration of the endometrial cavity, there appears to be an active fibrinolytic system in the endometrium mediated by plasmin through proteolytic cleavage of plasminogen by the activators urokinase-type plasminogen activator (uPA) and tissue-type plasminogen activator (tPA). These activators are regulated by plasminogen activator inhibitor 1 (PAI-1) and PAI-2, both of which are expressed in the endometrium. The presence of these fibrinolytic agents suggests that coagulation occurs but is rapidly reversed. Oestradiol stimulates uPA, whilst progesterone inhibits uPA (Casslen et al 1986). Furthermore, progesterone inhibits production of tPA, and this effect is amplified by production of PAI. Blood coagulation products have also been found to be severely depleted in menstrual fluid, suggesting consumption during menstruation (Hahn 1980).

Fibrin formation occurs during the process of menstruation (Beller 1971, Sheppard et al 1983). The high levels of fibrin degradation products in menstrual fluid are not solely due to direct digestion. Although menstrual blood contains

high levels of fibrin and fibrin degradation products, it contains no fibrinogen. Similar levels of protein C₁ inactivator, α_2 -macroglobulin and α_2 -antitrypsin have been found in peripheral and menstrual blood (Daly et al 1990). However, compared with peripheral plasma, lower levels of activated prothrombin, antithrombin, antiplasmin, plasminogen, protein C and factors V, VII, VIII and X have been reported in menstrual fluid (Rees et al 1985, Daly et al 1990).

Compared with peripheral plasma, menstrual blood has a marked increase in the level of tPA antigen with reduced levels of PAI. Levels of fibrinolytic enzymes in menstrual fluid vary according to cycle stage. Throughout the cycle, higher levels of tPA are found in the myometrium compared with the endometrium in the normal menstrual cycle (Sheppard 1992), whilst during the late secretory phase, several studies have demonstrated a significant increase in endometrial tPA levels.

The above mechanisms ensure that progesterone falls and oestradiol rises during menstruation. There is increased fibrinolytic activity in the endometrium of women with increased menstrual blood loss. The endometrium also generates factors that inhibit platelet aggregation and platelet adhesion. Such factors include prostacyclin, nitric oxide and platelet-activating factor (PAF) (Kelly et al 1984, Alecozay et al 1991).

Vasoconstriction

In the menstruating uterus, haemostatic events are strikingly different from the rest of the body (Christiaens et al 1980). At the onset of menstruation, damaged blood vessels are sealed by intravascular thrombi of platelets and fibrin. However, as menstruation progresses, the functional endometrium is shed and so these haemostatic thrombi are lost. Subsequently, during the first 20 h of menstruation, intense vasoconstriction of the spiral arterioles occurs; this assures haemostasis until regeneration of the endometrial surface is complete.

The role of prostaglandin F_{2 α} (PGF_{2 α}) in vasoconstriction is well established. The effects of the vasoconstricting PGF_{2 α} are balanced by those of the vasodilating prostaglandin E₂ (PGE₂). Concentrations of both these prostaglandins are increased in the luteal phase. Overproduction of the vasodilatory prostaglandins or reduced production of the vasoconstrictors is likely to lead to excessive blood loss at the time of menstruation. This is confirmed by work showing an elevated PGE₂/PGF_{2 α} ratio, increased endometrial PGE₂ or increased PGE₂ receptor concentrations in women with HMB (Smith et al 1981, Adalantado et al 1988). Steroid hormones influence endometrial prostaglandin synthesis, and the highest levels of the latter are found during menstruation. This is particularly true for PGF_{2 α} , the synthesis of which rises significantly during the secretory phase of the menstrual cycle under the influence of progesterone. It is also likely that the upregulation of the cyclo-oxygenase pathway impacts on angiogenesis in the endometrium.

Other vasoconstrictors, such as endothelins and PAF, may also contribute. Endothelins are powerful vasoconstrictors, and are found in human endometrium (Cameron et al 1992). They are thought to be involved in paracrine regulation of a number of endometrial functions, such as the induction of vascular and myometrial smooth muscle

contractions, fibroblast mitogenesis and the release of other paracrine agents (Ohbuchi et al 1995). Endothelins can also induce $\text{PGF}_{2\alpha}$. It has been proposed that as endometrial glandular epithelium breaks down during menstruation, stored endothelin gains access to the spiral arterioles, causing long-lasting vasoconstriction (Cameron and Davenport 1992).

PAF is present in the endometrium in the luteal phase and has an ambiguous effect on spiral arteriolar tone. PAF itself is a vasoconstrictor but it stimulates production of the vasodilator PGE_2 (Björk and Smedegård 1983, Smith and Kelly 1988).

Endometrial repair

Vasculature

Seventy percent of menstrual loss arises from the spiral arterioles, and most of this bleeding occurs within the first 3 days of menses (Haynes et al 1977). Concordantly, vessel repair begins within the first 2–3 days of the onset of bleeding. As might be expected, the endometrium is a rich source of angiogenic growth factors (Smith 1998). The fibroblast growth factor (FGF) and the vascular endothelial growth factor (VEGF) families are the best known.

Vascular endothelial growth factor

VEGF is a heterodimeric angiogenic growth factor which is expressed and secreted by a variety of endometrial cells, including macrophages and large decidualized cells. They cluster around the spiral arterioles during the late luteal phase (Gospodarowicz et al 1989, Charnock-Jones et al 1993). The variants of VEGF differ in their cellular localization.

Steroids and hypoxia regulate VEGF, with steroid regulation being around two orders of magnitude lower than that of hypoxia. VEGF mRNA is abundant in the endometrium at the time of menstruation (Charnock-Jones et al 1993). This upregulation probably follows the hypoxia induced by spiral arteriole vasoconstriction (Sharkey et al 2000). Its expression is followed by rapid angiogenesis when the functional endometrium is lost.

Vascular smooth muscle cells (VSMCs) in endometrium also express certain VEGF receptors. This provides a direct link between the development of spiral arterioles and VEGF-A expression. The finding of reduced proliferation of VSMCs in patients with HMB could be explained by altered VEGF-A expression. A novel angiogenic factor, endocrine gland VEGF, and its receptors have recently been reported to be expressed in the uterus (Battersby et al 2004).

Fibroblast growth factor

The FGF family consists of at least eight members, some of which are expressed in the endometrium and are hormone dependent with expression during the proliferative phase and reduction during the secretory phase (Basilico and Moscatelli 1992, Ferriani et al 1993). FGF synergizes with VEGFs in inducing angiogenesis (Pepper et al 1992). Inhibition of FGF action does not fully inhibit angiogenesis, but this is possible when anti-VEGF agents are used. VEGFs promote the release of FGF from the ECM. FGF and platelet-

derived growth factor are also known to stimulate angiogenesis, and have been demonstrated in the endometrium of a number of a species (Weston and Rogers 2000).

Angiopoietins

The angiopoietins are another family of molecules which influence vascular development and maintenance by stabilizing the endothelial cell and vascular smooth muscle structure (Suri et al 1998). Recently, expression patterns of the angiopoietin family in the human endometrium have been examined, although results have been conflicting, perhaps reflecting relatively low expression of these factors (Rogers and Abberton 2003). It is possible that this will alter the function of the VSMCs that are essential for controlling the blood loss at menstruation, and that HMB is due to aberrant build-up of VSMCs. Angiopoietin expression and signalling are regulated by the cyclo-oxygenase enzymes.

Epithelium

Once the functional layer of the endometrium is shed, the regeneration of all cell types (epithelial, endothelial and stromal) occurs rapidly. This regeneration occurs from the cells of the remaining basal layer, which acts as the germinal compartment of the functional endometrium (Chan et al 2004).

Given its dynamic nature, growth factors and cytokines are especially important in the development of the endometrium. In addition, tissue remodelling is dependent on the integrity of the ECM. Profound hormone-dependent tissue remodelling is seen in the endometrium, although currently there is no direct evidence linking disorders of tissue regeneration with HMB. Proliferation of the endometrium is most active during menstruation. The proliferation starts on day 2 in the basal glands and is complete by day 5, leaving a completely re-epithelialized endometrial surface. Various agents regulate this process, the best-known being epidermal growth factor (EGF). EGF is expressed in human epithelial cells throughout the cycle and stimulates endometrial epithelial proliferation (Haining et al 1991, Zhang et al 1995). Oestradiol induces the expression of EGF and its receptor. However, during menstruation, when the concentration of oestradiol is at its lowest, there are sufficient amounts of residual EGF remaining in the epithelial cells as growth continues before oestradiol levels increase during the proliferative phase. Additionally, EGF has been shown to mimic the proliferative effect of oestradiol in the endometrium of transgenic mice lacking the oestradiol receptor (Ignar-Trowbridge et al 1993). Numerous other growth factors (insulin-like growth factor, FGF) and their binding proteins are expressed in the endometrium, and all promote cell proliferation. The complexities of tissue remodelling suggest that altered wound healing may be a factor in the aetiology of HMB, and its role warrants further investigation.

Matrix

The ECM is a dynamic structure composed of collagens, fibronectin, laminin, gelatins, entactins, hyaluronic acid and proteoglycans, all of which provide the tissue with structural integrity.

Integrins are the agents which link the ECM with epithelial cells of the endometrium (Hynes 1987, Lessey et al 1992). The MMPs are a highly regulated family of calcium and zinc endopeptidases, which are able to degrade most components of the ECM in the activated state. These enzymes are active in normal and pathological processes involving tissue remodelling. MMP activity is greatest during days 1–4 of the cycle. Progesterone withdrawal and migratory leukocytes activate some MMPs, and this may be a significant step in the initiation of menstruation. Local release of agents such as MMP-1 and MMP-3 from stromal cells may activate other proteases released from the invading neutrophils (Schatz et al 1999). This is supported by the presence of substantially more latent MMP-9 than active MMP-9 before menstruation (Rigot et al 2001). Abnormalities in the dynamic turnover of collagen production are likely to be important in menstrual upset given their importance in other vascular and fibrotic processes.

Normal Menstrual Cycle

The majority of cycles lie between 24 and 32 days, and a normal cycle is considered to last for 28 days. Menstrual cycle length varies during reproductive life, being most regular between the ages of 20 and 40 years. It tends to be longer after the menarche and shorter as the menopause approaches. The mean menstrual blood loss per menstruation in a healthy Western European population ranges between 37 and 43 ml; 70% of the loss occurs in the first 48 h. Despite large interpatient variability, loss between consecutive menses in the same woman does not vary largely (Figure 31.3). Only 9–14% of women lose more than 80 ml per menses, and 60% of these women are actually anaemic. The upper limit of normal menstruation is thus taken as 80 ml per menses (Rybo 1966). However, total fluid loss (mucus, tissue, etc.) may be considerably more than the blood loss alone and amounts vary. These parameters have been reviewed recently (Fraser and Inceboz 2000).

Figure 31.3 The variability in menstrual blood loss in a single individual: values for 12 consecutive periods.

From Hallberg L, Nilsson L 1964 Consistency of individual menstrual blood loss. *Acta Obstetrica et Gynecologica Scandinavica* 43:352–359, Blackwell Science.

During the first day or two of the menses, uterine contractility is at its greatest. This may aid expulsion of the degenerating endometrium from the uterus. Activity is extremely variable between women, although it is remarkably constant between menses in the same woman. There is no objective method of separating normal and abnormal contractility; normal contractility does not cause debility to a woman, although mild discomfort may occur.

The pattern of spontaneous myometrial contractions varies during the menstrual cycle (Lumsden et al 1983). Time-lapse ultrasound studies have shown that propagated myometrial contractions in the non-pregnant uterus emanate from the JZ. The frequency and direction of these contractions depend on the phase of the cycle. In the follicular and periovulatory phases, cervicofundal subendometrial contractions can be seen, the amplitude and frequency of which increase notably towards ovulation. Short, asymmetrical myometrial waves are present during the luteal phase, but propagated fundocervical subendometrial contraction waves are noted during menstruation (de Vries et al 1990, Chalubinski et al 1993).

Kunz et al (1996) demonstrated the role of preovulatory cervicofundal contractions in assisting the rapid transport of sperm through the female reproductive tract. Others have postulated that the asymmetrical myometrial peristalsis during the luteal phase serves to maintain the developing blastocyst within the uterine fundus. The role of fundocervical contractions during menstruation is likely to be important in controlling menstrual flow and limiting retrograde menstruation (Chalubinski et al 1993).

Abnormal Menstruation

This part of the chapter will consider abnormalities of menstrual bleeding including HMB, with particular reference to dysfunctional uterine bleeding (DUB) and dysmenorrhoea. The defects most usually associated with infertility, e.g. oligo- and amenorrhoea, will not be discussed further.

Heavy menstrual bleeding (HMB)

In the past, this was known as 'menorrhagia' but this term means different things to different people and should be avoided.

The causes of HMB fall into four categories:

- DUB;
- pelvic pathology;
- medical disorders; and
- coagulation disorders.

Dysfunctional uterine bleeding

Disturbances in the pattern of menstruation are a common clinical presentation for abnormalities of the hypophyseal-pituitary-ovarian axis. DUB is defined as HMB, in the absence of recognizable pelvic pathology, pregnancy or general bleeding disorder, which interferes with a woman's physical, social, emotional and/or material quality of life. It commonly occurs at the extremes of reproductive life

(adolescence and perimenopausally). The abnormalities of ovarian activity may be classified as anovulatory [i.e. inadequate signal, such as in polycystic ovary syndrome (PCOS) or premenopausally, and impaired positive feedback, such as in adolescence] and ovulatory.

Anovulatory dysfunctional uterine bleeding

Occasionally, anovulatory cycles occur in all women. Chronic anovulation, however, is associated with an irregular and unpredictable pattern of bleeding ranging from short cycles with scanty bleeding to prolonged periods of irregular heavy loss. Normal bleeding occurs in response to withdrawal of both progesterone and oestradiol. If ovulation does not occur, the absence of progesterone results in an absence of secretory changes in the endometrium, accompanied by abnormalities in the production of steroid receptors, prostaglandins and other locally active endometrial products. Unopposed oestrogen gives rise to persistent proliferative or hyperplastic endometrium, and oestrogen withdrawal bleeding is characteristically painless and irregular. It tends to occur at the extremes of reproductive life but is rare at other times. Only 20% of those cycles with excessive menstrual blood loss are anovulatory (Haynes et al 1979); this same study failed to demonstrate any abnormalities in gonadotrophin or circulating steroid concentrations. In anovulatory cycles, the endometrium is unable to produce factors whose synthesis is controlled by progesterone, such as $\text{PGF}_{2\alpha}$ (Smith et al 1982). This may account for the painless nature of the bleeds. Ovulation occurs in response to the mid-cycle surge of luteinizing hormone (LH). If this fails to occur due to insufficient oestradiol secretion or impaired positive feedback, ovulation will not occur.

Failure of follicular development

Follicular development which is insufficient to produce an oestrogen signal strong enough to induce an LH surge is one of the common reasons for the irregularities in menstrual cycle pattern in premenopausal women. This occurs perimenopausally and in PCOS (see Chapter 18 for information regarding the aetiology and treatment of PCOS).

Anovulatory bleeding may be associated with cystic glandular hyperplasia of the endometrium (see Figure 31.2E). This occurs in some older women and also in peripubertal girls where unopposed oestrogen secretion occurs. The first few cycles after the menarche are commonly anovulatory. However, if anovulation persists, a long period of amenorrhoea is accompanied by endometrial hyperplasia. This is probably a result of multiple follicular development (multicystic ovaries) with failure of antral follicle formation. Endometrial hyperplasia may cause excessive bleeding, anaemia, infertility and even cancer of the endometrium.

In the younger patient (<40 years of age) with anovulatory HMB, assessment of the hypothalamic–pituitary–ovarian axis is indicated. The diagnosis of PCOS has increased over recent years, with the finding of altered LH/follicle-stimulating hormone ratios in the follicular phase of the cycle and the identification of micro- and macrocystic disease by vaginal ultrasound. Obesity alone can produce a similar picture in the absence of any other sign of PCOS.

Ovulatory dysfunctional uterine bleeding: idiopathic bleeding

As described above, an important factor in the control of menstrual blood loss is vasoconstriction. It appears that there are a number of endometrial products which alter the degree of vasoconstriction, and thus may affect the volume of menstrual blood lost. In the mid-1970s, a relationship between prostaglandin production and HMB was suggested by work showing that total endometrial prostaglandin content was proportional to menstrual loss. It appears that a shift in endometrial conversion of endoperoxide from the vasoconstrictor prostaglandins ($\text{PGF}_{2\alpha}$) to the vasodilator prostaglandins (PGE_2 or prostacyclin) occurs. However, it is likely that it is not only prostaglandins that are of importance, and work is now being performed on the role of endothelin in heavy menstrual loss. Endothelins are very potent vasoconstrictors that are produced within the endometrial vessels; their receptors are also present, although it is not yet clear whether either of these two factors differ in women with heavy menstrual loss. Although studies to date are limited, Marsh (1996) showed reduced immunostaining for endothelin in the endometrium of women with HMB, implicating this peptide in the pathophysiology of increased menstrual blood loss. This is a rapidly changing area of knowledge, and it is likely that other elements will come to light which will be significant. According to Jabour et al (2006): 'Further challenge in the future will be the development of experimental strategies that will allow us to assess the exact role of the various factors deduced from gene mining studies in menstrual function/dysfunction and which of these gene pathways constitute a sensible target for novel therapeutic application in the clinic.'

It is still uncertain why there is a difference in production of local factors in those with heavy menstrual loss compared with those with normal loss. Interest has centered on the role of steroid hormones, but it has been impossible to demonstrate either a difference in the circulating levels of oestradiol and progesterone or in the receptor concentration within the endometrium (Critchley et al 1994). It is possible that there is a genetic difference altering the production of local hormones and growth factors, or that there is a multifactorial aetiology. Reference has been made above, in discussion of the control of menstrual blood loss, to areas of research which may throw new light on the mechanism of HMB.

Heavy menstrual bleeding in the presence of pelvic pathology

HMB is thought to be associated with uterine fibroids, adenomyosis, pelvic infection, endometrial polyps and the presence of a foreign body such as an intrauterine contraceptive device (IUD). In addition, the rare conditions of myometrial hypertrophy and vascular abnormality may be associated with severe, even life-threatening HMB. However, objective evidence of HMB in most of these situations is limited. In women with menstrual blood loss greater than 200 ml, over half will have fibroids, although only 40% of those with adenomyosis actually have menstrual blood loss in excess of 80 ml per menses. It is not clear if chronic pelvic inflammatory disease or endometrial polyps are associated with above-average blood loss.

Although vasoactive peptides may contribute to HMB associated with pathology, non-steroidal anti-inflammatory drugs (NSAIDs) are less effective in HMB associated with IUD presence than in DUB, making it likely that other factors are also important.

Medical problems

HMB is associated with various endocrine disorders such as hypothyroidism (thyrotoxicosis is more commonly associated with cycle disturbance) and Cushing's disease, although the mechanism is unknown. Thyroid disease is often considered to be a common cause for HMB, but it is rare for thyroid disease to present in this way without other associated symptoms, e.g. weight gain, hair loss, constipation, etc. Thyroid function tests do not need to be performed in all women presenting with HMB.

Coagulation disorders

Although certain haemorrhagic conditions, e.g. thrombocytopenic purpura and von Willebrand's disease, are associated with an increased incidence of HMB, coagulation disorders have a variable effect overall. There is no impairment of systemic coagulation in those with excess menstrual loss, nor are fibrin degradation products elevated in the menstrual fluid of those with heavy menstrual loss (Bonnar et al 1983). In women with thrombocytopenia, menstrual blood loss correlates broadly with platelet count at the time of the menses. Splenectomy has been known to reduce menstrual blood loss dramatically in these patients.

Women with factor VII deficiency exhibit a spectrum of bleeding symptoms, with HMB being one of the most common (Kulkarni et al 2006). There is no need to test for these routinely unless HMB has been present from adolescence or the woman encountered bleeding problems with dental extraction.

Dysmenorrhoea

Dysmenorrhoea comes from Greek and means 'difficult monthly flow', but is now taken to mean painful menstruation. It is a symptom complex, with cramping lower abdominal pain radiating to the back and legs, often accompanied by gastrointestinal and neurological symptoms as well as general malaise. As with HMB, it may be associated with pathology or may be idiopathic in origin.

Idiopathic (primary) dysmenorrhoea

There are many different theories regarding why women suffer from dysmenorrhoea. The following factors may be of importance.

Uterine hyperactivity

The significance of uterine hyperactivity in women with dysmenorrhoea was first proposed in 1932. Since then, there has been much research which suggests that women with dysmenorrhoea have increased uterine activity during menstruation (Novak and Reynolds 1932, Filler and Hall 1970). Patients often describe the pain as 'labour-like', and an increase in uterine contractility can be demonstrated by measuring intrauterine pressure in those with dysmenor-

rhoea compared with women without dysmenorrhoea (Lumsden and Baird 1985). The increased uterine contractility also appears to be related to uterine blood flow and the presence of pain (Åkerlund and Andersson 1976).

During the reproductive years, the myometrium is structurally and functionally polarized (see above). Using transvaginal ultrasound scanning or MRI, it is possible to delineate between the myometrial zones (Brosens et al 1998, Lesny et al 1999).

Patients with endometriosis and adenomyosis have been found to have structural and functional abnormalities of the JZ (Brosens et al 2000). Leyendecker et al (1996) demonstrated marked hyperperistalsis of the JZ during the early- and mid-follicular phase in women with endometriosis, associated with a marked increase in the transport of inert particles from the vaginal depot to the peritoneal cavity.

Dysmenorrhoeic patients have been found to exhibit profound structural changes in the JZ, including irregular thickening, and smooth muscle hyperplasia characterized by closely packed smooth muscle fibres which are poorly oriented and less vascular than the smooth muscle of normal inner myometrium (Togashi et al 1989, Brosens et al 1998). Consequently, the term 'junctional zone hyperplasia' was coined for this disorder (Brosens et al 1998).

Dysperistalsis and hyperactivity of the uterine JZ are important mechanisms of primary dysmenorrhoea, and possibly menstrual pain associated with adenomyosis and endometriosis (Brosens et al 2000).

Endothelins

Endothelins are potent uterotonins in the non-pregnant uterus. They are thought to be involved in the induction of myometrial smooth muscle contraction in a juxtacrine fashion. The greatest density of endothelin-binding sites is found on glandular epithelium in the endomyometrial junction, and recent evidence suggests that endothelins in the endometrium can induce $\text{PGF}_{2\alpha}$ and further endothelin release in a paracrine and autocrine fashion (Bacon et al 1995). Local ischaemia could further increase the expression of endothelins and prostaglandins, which could further aggravate uterine dysperistalsis.

Prostaglandins

It has been shown that dysmenorrhoeic women have increased endometrial synthesis of $\text{PGF}_{2\alpha}$ and enhanced concentrations of $\text{PGF}_{2\alpha}$ and PGE_2 in menstrual blood compared with asymptomatic women (Lundstrom and Green 1978, Lumsden et al 1983). $\text{PGF}_{2\alpha}$ is a potent oxytocic and vasoconstrictor. When administered into the uterus, it will give rise to dysmenorrhoea-like pain and occasionally menstrual bleeding. Menstrual fluid $\text{PGF}_{2\alpha}$ concentrations also correlate with uterine work during the menses in women with dysmenorrhoea (Lumsden et al 1983). These properties of $\text{PGF}_{2\alpha}$ could thus lead to 'angina' of the myometrium. The role of PGE_2 is less clear, although its administration may increase the sensitivity of nerve endings.

The reason for the abnormal prostaglandin levels is unknown. Primary dysmenorrhoea occurs almost exclusively in ovulatory cycles, and steroid hormones affect both uterine prostaglandin concentration and myometrial contractility. However, no consistent abnormality of hormone levels has been demonstrated in those with dysmenorrhoea. Treatment

with prostaglandin synthetase inhibitors reduces uterine $\text{PGF}_{2\alpha}$ production, uterine activity and dysmenorrhoea.

Vasopressin

The treatment of HMB with desmopressin is efficacious and safe if patients are instructed to self-administer the agent only during the first 2 or 3 days of heavy menstrual blood loss, for a maximum of three to four doses and with no more than two consecutive administrations during a 12-h interval (Rodeghiero 2008).

There are other stimulants of the non-pregnant uterus, such as vasopressin, a vasoconstrictor that also stimulates uterine contractility. On the first day of menstruation, circulating vasopressin levels are higher in those with dysmenorrhoea than in those without dysmenorrhoea (Åkerlund et al 1979). Infusion of hypertonic saline results in increased uterine contractility and pain in women with dysmenorrhoea as a result of stimulation of endogenous vasopressin release, as well as a reduction in concentrations of $\text{PGF}_{2\alpha}$ metabolites. Preliminary studies also indicate that vasopressin analogues may have a place in the treatment of dysmenorrhoea.

Other factors

PAF is present in a higher concentration in women with dysmenorrhoea (Migram et al 1991). This is somewhat surprising as PAF inhibits $\text{PGF}_{2\alpha}$ production, although it does stimulate overall phospholipid metabolism, and other factors, which have not been measured, may be elevated.

Another factor of potential importance is the destruction of nerve endings in the myometrium and cervix by pregnancy. This may explain the observation that primary dysmenorrhoea is relieved by the birth of a baby. The literature suggests that psychological and physical causes for dysmenorrhoea are mutually exclusive. The evidence for physical factors is strong, treatment is very effective and it is unlikely that psychological problems would be removed simply by taking tablets. However, recurring, debilitating pain may cause depression and anxiety in women of any age.

Secondary dysmenorrhoea

As with HMB, this may be associated with uterine and pelvic pathology such as fibroids, the presence of an inert copper-containing IUD, pelvic inflammatory disease, adenomyosis, endometriosis or cervical stenosis. The cause of the pain is not always clear. Abnormal uterine contractility has been observed in those with fibroids, and prostaglandins may be involved when dysmenorrhoea is associated with an IUD, pelvic inflammatory disease, adenomyosis and possibly endometriosis. However, the use of prostaglandin synthetase inhibitors is less effective in the presence of pathology, making it likely that other factors also exist.

Those women presenting with dysmenorrhoea who have no other complaints or abnormalities on examination can be safely treated without further investigation. Pierzynski et al (2006) have shown that tamoxifen, a selective oestrogen-receptor modulator, directly inhibits uterine contractions, causing improvement in uterine blood flow and a decrease in menstrual pain and cramps. This could be considered for application in selected groups of dysmenorrhoeic women; for instance, carriers of breast-cancer-associated

antigen genes, breast cancer survivors or women with advanced endometriosis (Pierzynski et al 2006).

Letzel et al (2006) reported that aceclofenac (100 mg) and naproxen (500 mg) effectively reduced the pain associated with primary dysmenorrhoea, and both were more effective than placebo at easing menstrual pain assessed by various pain relief criteria. Laparoscopy is indicated for those with a provisional diagnosis of endometriosis or pelvic inflammatory disease. Hysteroscopy, endometrial sampling and examination under anaesthetic are only required if uterine abnormality is suspected. The standard treatment for dysmenorrhoea (prostaglandin synthetase inhibitors and the oral contraceptive pill) is so effective that laparoscopy in treatment failures will often demonstrate previously unsuspected abnormalities such as mild endometriosis, even in teenage girls.

Epidemiology of Menstrual Abnormality

The distribution of blood loss for a normal population shows a positively skewed distribution, as mentioned above (Figure 31.4) (Cole et al 1971). Age *per se* does not influence menstrual blood loss until the sixth decade (Figure 31.5, Table 31.1). This may be due to an increased incidence of pathology (e.g. fibroids or perimenopausal endocrine abnormalities). An hereditary influence has been demonstrated following twin studies, and parity is thought to be an important factor; parous women have greater menstrual blood loss than nulliparous women. Uterine pathology, particularly fibroids, is a well-documented cause for HMB, although endometrial pathology is rather uncommon in these women; it is found as a reasonable cause for HMB in approximately 6% of cases.

The variation between menses for an individual (intra-menses) is between 20% and 40%. Approximately 90% of blood is lost during the first 3 days of the menses in women with normal blood loss and women with HMB. These studies are based on objective measurement of menstrual blood loss, which is rarely done except for research purposes

(Hallberg and Nilsson 1964). New methods of measuring menstrual symptoms are being designed in order to allow for better objective assessment, with consideration given to the variety of symptoms that contribute to the overall complaint such as irregularity, HMB, pain and premenstrual syndrome.

The results of epidemiological studies performed over the last 50 years give a variable incidence for dysmenorrhoea. This is because pain is a subjective symptom and cannot be assessed accurately by an outsider. Different women will react to the same pain in different ways. How each woman perceives the pain will vary according to her individual circumstances. In addition, the definition and diagnosis allow different interpretations by different workers. Severe dysmenorrhoea, which causes disruption of daily routine with time off work or study, occurs in 3–10% of 19-year-olds (Andersch and Milsom 1982), while mild discomfort occurs in the majority of women. The relative risk of dysmenorrhoea in those who have smoked for 10–20 years is up to six-fold higher than the risk in non-smokers (Parazzini et al 1994). The incidence of dysmenorrhoea is inversely correlated with age, and parous women are less likely to report the condition. There is no correlation between the incidence of emotional stress factors and dysmenorrhoea.

Box 31.1 Clinical history

Symptoms suggestive of other pathology

- Irregular bleeding
- Sudden change in blood loss
- Intermenstrual bleeding
- Postcoital bleeding
- Dyspareunia
- Pelvic pain
- Premenstrual pain

Risk factors for endometrial cancer

- Tamoxifen
- Unopposed oestrogen treatments
- Polycystic ovary syndrome
- Obesity

Presentation

Clinical history

Menstrual problems are a common reason for presentation to both general practitioners and gynaecologists. A history of heavy, regular, cyclical menstrual blood loss over several consecutive cycles without additional irregular bleeding suggests DUB. A detailed history may suggest other underlying pathology; for example, heavy painful menses and dyspareunia might suggest endometriosis, whilst heavy bleeding with a vaginal discharge and abdominal pain points to pelvic inflammatory disease.

Risk factors for endometrial carcinoma should be noted carefully in the history (Box 31.1, Figure 31.6).

Examination

General examination may reveal signs of hypothyroidism, anaemia or blood clotting disorders. Abdominal and pelvic examination is only mandatory in women complaining of HMB if structural abnormality is expected (National Institute for Health and Clinical Excellence 2007). Clues to diagnosis may be revealed on pelvic examination. A tender fixed uterus may suggest endometriosis or pelvic inflammatory disease, whilst fibroids can often be palpated. A symmetrically enlarged uterus is more typical of adenomyosis or endometrial carcinoma. Atrophic and inflammatory vulvar and vaginal lesions can be visualized, and cervical polyps and invasive lesions of cervical carcinoma that may present with irregular bleeding can be seen. Anaemia may also be present since HMB is the most common cause of iron-deficiency anaemia in the Western world. HMB may arise because of disorders of the haemopoietic system, as described above.

Investigation

Haemoglobin concentration should be determined in all women with HMB, and iron supplementation should be given if required. Although thyroid disease is a cause of

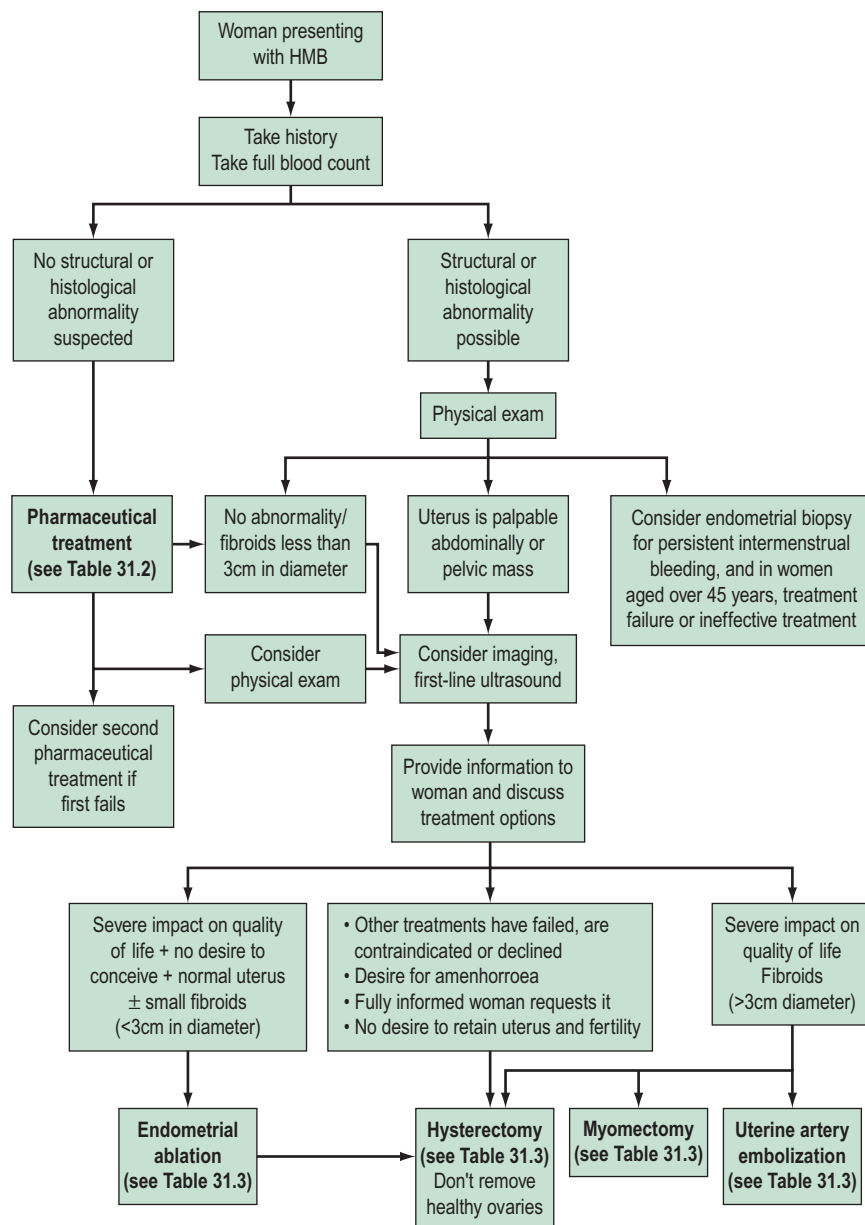

Figure 31.6 National Institute for Health and Clinical Excellence care pathway for heavy menstrual bleeding (HMB).

Source: National Institute for Health and Clinical Excellence 2007 Clinical Guideline No. 44. Heavy Menstrual Bleeding at www.nice.org

menstrual derangement in some women, screening thyroid-stimulating hormone and thyroxine measurements are not justified unless there are other features in the history suggestive of thyroid disease (Fraser et al 1986, National Institute for Health and Clinical Excellence 2007). Similarly, routine screening for bleeding diatheses is not appropriate.

Assessment of the uterine cavity

The main indication for assessment of the uterine cavity is to exclude sinister pathology, the likelihood of which increases with age in the presence of risk factors. A history of irregular bleeding or the presence of risk factors for endometrial cancer will determine the need for endometrial assessment.

A wide array of methods are available for endometrial assessment including:

- ultrasonography for evaluation of uterine architecture and endometrial thickness;
- endometrial sampling;
- hysteroscopy and endometrial biopsy;
- sonohysterography;
- cytological examination; and
- dilatation and curettage (D&C) alone should not be used as a diagnostic tool (National Institute for Health and Clinical Excellence 2007).

Ultrasonography

Ultrasonography allows evaluation of the uterine architecture and endometrial thickness, and is an important adjunct to endometrial sampling. Transvaginal ultrasound scanning is a useful tool allowing better resolution than abdominal scanning because of the close proximity of the ultrasound

probe with the pelvic organs. It has a specificity of 96% and a sensitivity of 89%. Endometrial thickness is only of value after the menopause. Ultrasound assessment should be combined with endometrial biopsy when endometrial thickness exceeds 5 mm.

Abnormalities on pelvic examination should be investigated by ultrasound, and laparoscopy if required.

Endometrial sampling

In 1882, Moriche obtained the first endometrial sample using a catheter. Endometrial biopsy has been performed in an outpatient setting since 1935. The 1970s saw the introduction of the Vabra curette, followed by the Pipelle sampler in the 1980s. The Pipelle is easier to use and more comfortable for the patient but it only samples 4% of the endometrium, whereas the Vabra aspirator samples approximately 40%. The main disadvantage of blind sampling of the uterine cavity is that pathology such as polyps or submucous fibroids may be missed.

The risk of endometrial carcinoma in women with perimenopausal HMB is approximately 1%; hence, all women with irregular bleeding that is unresponsive to treatment need endometrial assessment. Although women under 40 years of age have a very low risk of developing endometrial carcinoma, further investigation may be needed in high-risk symptomatic women (Royal College of Obstetricians and Gynaecologists 1994).

Hysteroscopy

Hysteroscopy facilitates intrauterine surgical procedures such as endometrial ablation. Hence, it has long been accepted into UK gynaecological practice for diagnostic and therapeutic purposes. Hysteroscopy and directed biopsy appear to be superior in identifying benign endometrial pathology (Gimpleson and Rappold 1988, Loffer 1989). More pertinently, in a significant minority of women with endometrial carcinoma, the diagnosis is missed when conventional curettage is used (Stovall et al 1989), and it appears that hysteroscopy and directed biopsy is more sensitive in the diagnosis of this condition. Ultrasound is better at identifying fibroids unless it is intracavity, and hysteroscopy should only be used when ultrasound is unsatisfactory.

The development of a narrow diameter (4 mm) scope allows this investigation to be performed in the outpatient setting in a carefully selected patient group following counselling (Taylor and Hamou 1983). Patient selection is important to maximize the success of the procedure; for example, women with a previous cervical cone biopsy or Manchester repair may have cervical stenosis, making passage of the hysteroscope through the internal os difficult.

Hysteroscopy should always be combined with an endometrial biopsy. It should be avoided during menstruation as blood in the cavity obscures the view. The cavity is distended with either gas or fluid. In addition, hysteroscopy enables detection of polyps, submucous fibroids and uterine synechiae in women who have previously had multiple previous 'negative' curettages.

These studies provide increasing evidence that hysteroscopy and endometrial sampling in combination is a superior

diagnostic tool. This has therefore replaced D&C as the investigation of choice in menstrual disorders (Lewis 1990, 1994).

Sonohysterography

In sonohysterography, ultrasound is performed following injection of saline by a narrow catheter into the uterus. This may increase the sensitivity of transvaginal ultrasonography. Hence, sonohysterography has been used to evaluate the endometrial cavity for polyps, submucous fibroids and uterine abnormality, especially septate and subseptate uterus.

Cytologic examination

Cytological examination is normally used to diagnose asymptomatic intraepithelial lesions of the cervix. This is not reliable for the diagnosis of endometrial pathology. The presence of endometrial cells in the smear of a postmenopausal woman is abnormal, unless she has been exposed to exogenous oestrogen. Similarly, women in the secretory phase of the menstrual cycle should not shed endometrial cells. However, a smear that is positive or suspicious for endometrial cancer needs evaluation.

The investigation of women presenting with heavy menstrual loss is summarized in Figure 31.6.

Quantification of Menstrual Blood Loss

The objective assessment of menstrual blood loss is rarely made, except for research purposes. However, menstrual blood loss can be assessed either in a semiquantitative manner, relying on the patient's assessment of the bleeding, or by the use of pictorial aids (Higham et al 1990). The pictorial method has been shown to correlate well with the gold standard alkaline haematin method (Higham et al 1990, Wyatt et al 2001). However, this correlation has also been challenged (Reid et al 2000). Attention is being given to the development of aids, including the use of hand-held computers, to assess the menstrual complaint as a whole, which consists of more than heavy bleeding. Many women also complain of pain and premenstrual syndrome. Again, these are not yet available for general use.

Treatment

General principles of management

A detailed history should be taken and examination performed as required. The importance of desiring a pregnancy when using the oral contraceptive pill, Depo-Provera, Implanon and IUDs must be considered. The most likely cause of the abnormal bleeding, the work-up strategy and the treatment will depend upon the woman's age, medical condition and desire for future fertility. Women should be given information prior to an outpatient appointment. Treatment options should be discussed, and rapid, safe and effective treatment should be instituted to improve menstrual problems and quality of life.

Medical treatment

Current medical therapy falls into two broad groups: non-hormonal (prostaglandin synthetase inhibitors, antifibrinolytics and ethamsylate) and hormonal (progestogens, oral contraceptives, hormone replacement therapy, danazol, gestrinone, GnRH analogues) (see Table 31.2). Non-hormonal treatment may be taken during menstruation, which avoids teratogenicity and is therefore suitable for women who wish to conceive. Some women, once reassured that there is no major pathology, will require no further treatment.

Non-hormonal treatment

Prostaglandin synthetase inhibitors

NSAIDs remain a popular choice for the treatment of HMB (Coulter et al 1995). Their principal mechanism of action is to decrease endometrial prostaglandin concentrations. The endometrium is a rich source of PGE₂ and PGF_{2α} and a number of studies have shown that prostaglandin concentrations are greater in the endometrium of women with HMB than they are in the endometrium of women with normal blood loss (Cameron and Norman 1995).

There are four groups of prostaglandin synthetase inhibitors, of which the fenamates are the most widely used. These are unique amongst the prostaglandin synthetase inhibitors in that, in addition to inhibition of prostaglandin synthesis, they bind and block the prostaglandin receptor (Rees et al 1988). Menstrual blood loss is reduced by a median of 25–40% in three-quarters of women with HMB (Figure 31.7). The beneficial effect of mefenamic acid on menstrual blood

loss (and other symptoms including dysmenorrhoea, headache, nausea, diarrhoea and depression) can be long term, but if it is not effective within 3 months, treatment should be stopped. Side-effects, mainly gastrointestinal (dyspepsia, nausea and diarrhoea), are mild and not frequently reported.

In summary, mefenamic acid and related compounds are effective first-line medical treatments for women with HMB. The mean reduction of menstrual blood loss is not as great as that for antifibrinolytic agents, but the NSAIDs have a lower side-effect profile in otherwise healthy women and are more effective for the treatment of pain.

Antifibrinolytics

As discussed above, the endometrium possesses an active fibrinolytic system which is more active in the endometrium of women with HMB than in those without HMB. Antifibrinolytic agents such as tranexamic acid reduce menstrual loss by approximately 50%. This is greater than the reduction following administration of prostaglandin synthetase inhibitors (Ylikorkala and Viinikka 1983, Milsom et al 1991).

The incidence of adverse effects is dose dependent. One-third of women experience gastrointestinal side-effects following treatment with tranexamic acid 3–6 g/day. As 90% of menstrual blood is lost in the first 3 days of full flow, dose-related side-effects can be reduced by limiting the number of days on which the drug is taken to the first 3 or 4 days of the menses. Serious side-effects are uncommon. No increase in the incidence of thromboembolic disease has been seen in women of reproductive age in Scandinavia, where tranexamic acid has been used since the early 1970s as a first-line treatment for HMB (Rybo 1991). Antifibrinolytic agents therefore represent a relatively effective first-line treatment to reduce the degree of menstrual bleeding.

Ethamsylate

Systematic evaluation clinical trials suggest that ethamsylate is ineffective and its use in HMB is no longer recommended.

Hormonal treatment

Hormonal treatments for HMB are summarized in Box 31.2.

Progestogens

Synthetic progestogens are widely used to treat HMB. They have an endometrial suppressive effect, resulting in small depleted glands lined with a thin epithelium and decidualized transformation of the stroma.

Cyclical progestogens

It has been shown that low-dose, short-duration therapy of oral progestogens during the luteal phase is ineffective for the reduction of menstrual loss (Figure 31.8) (Cameron et al 1990). However, they may be successful if given at a dose of 5 mg three times daily from days 5 to 26 of the cycle. On this regime, menstrual loss can be reduced by up to 30% (Irvine et al 1998). Cyclical progestogens can be used to regulate the onset of bleeding and are useful for those with an irregular, unpredictable cycle.

Continuous progestogens

Various continuous preparations are available including oral tablets, long-acting intramuscular injections and subdermal

Figure 31.7 Percentage change in menstrual blood loss (mean of two cycles) of women receiving (A) norethisterone (5 mg bd, days 19–25) and (B) mefenamic acid (250 mg tds, days 1–5).

Table 31.2 Pharmaceutical treatments proven to reduce menstrual bleeding*

Discuss hormonal and non-hormonal options, and provide time and support to help the woman to decide which option is best for her.

Pharmaceutical treatment	How it works	Is it a contraceptive?	Will it impact on future fertility?	Potential unwanted outcome experienced by some women [§]
First line	Levonorgestrel-releasing intrauterine system ^{†‡} A device which slowly releases progestogen and prevents proliferation of the endometrium. A physical examination is needed before fitting	Yes	No	Common: irregular bleeding that may last for over 6 months; hormone-related problems such as breast tenderness, acne or headaches, if present, are generally minor and transient. Rare: uterine perforation at the time of insertion
Second line	Tranexamic acid (non-hormonal). Can be used in parallel with investigations. If no improvement, stop treatment after three cycles Non-steroidal anti-inflammatory drugs (non-hormonal). If no improvement, stop treatment after three cycles. Can be used in parallel investigations. Preferred over tranexamic acid dysmenorrhoea	No	No	Less common: indigestion, diarrhoea and headache Common: indigestion and diarrhoea. Rare: worsening of asthma in sensitive individuals, and peptic ulcer with possible bleeding and peritonitis
	Combined oral contraceptives [‡]	Yes	No	Common: mood change, headache, nausea, fluid retention and breast tenderness
Third line	Oral progestogen (norethisterone) [‡] Injected progestogen ^{†‡}	Yes [‡]	No	Common: weight gain, bloating, breast tenderness, headaches and acne (but usually minor and transient). Rare: depression
	Intramuscular injection that prevents proliferation of the endometrium	Yes	No	Common: weight gain, irregular bleeding, amenorrhoea and premenstrual-like syndrome (including bloating, fluid retention and breast tenderness). Less common: bone density loss
Other	Gonadotrophin-releasing hormone analogue. If used for more than 6 months, add-back hormone replacement therapy is recommended	No	No	Common: menopausal-like symptoms (e.g. hot flushes, increased sweating and vaginal dryness). Less common: osteoporosis, particularly trabecular bone with use for more than 6 months

implants. Irregular bleeding and oligomenorrhoea (in many cases, amenorrhoea) are common consequences. Progestogen-only contraceptive pill users may also report a decrease in their menstrual loss.

Intrauterine progestogens

The most recently described medicated device is the levonorgestrel intrauterine system (LNG-IUS; Mirena). This delivers LNG 20 µg to the endometrium every 24 h in a sustained-release formulation that can last for up to 5 years (Luukkainen et al 1986). Direct administration of the progestogen to the uterus results in minimal systemic absorption (Andersson and Rybo 1990), giving a better side-effect profile (Cheng Chi 1991).

The efficacy of the LNG-IUS for the treatment of HMB compares well with transcervical resection of the endometrium (TCRE) at 12 months post treatment (Crosignani et al 1997, Rauramo et al 2004). It has also been suggested that it might be an acceptable alternative to hysterectomy (Lahteenmaki et al 1998). Moreover, it also appears to be cost-effective when compared with thermal balloon ablation for treatment of HMB (Brown et al 2006).

The LNG-IUS has a local effect on the endometrium causing endometrial glandular atrophy, stromal decidualization and epithelial cell inactivation. This is seen within 1 month of insertion and occurs independently of ovarian

activity (Silverberg et al 1986). When removed, the endometrium recovers quickly and biopsies taken at 1–3 months show no sign of progesterone administration, regardless of duration of treatment. The LNG-IUS has a weak effect on ovarian function, with ovulation continuing in approximately 75% of women. The most significant side-effect is irregular bleeding that may present for more than 6 months; women require careful counselling prior to insertion if this is not to lead to removal of the device.

Oestrogen/progestogen regimes

The combined oral contraceptive pill is widely used to treat HMB. It causes endometrial atrophy and, in this way, reduces endometrial prostaglandin synthesis and fibrinolysis. Menstrual loss can be reduced by as much as 50% (Fraser and McCarron 1991). Although the use of the low-dose oestrogen pill in the management of HMB has been affected by adverse publicity associated with its use in older women, it is now felt to be quite safe in women of any age who are not obese, do not smoke and are not hypertensive. It has the added advantage of providing a regular menstrual cycle and being effective in the treatment of dysmenorrhoea (Ekstrom et al 1989, Davis 2005). The limiting factor is that many of the women will have been sterilized and are therefore reluctant to continue with something they see as a contraceptive agent. Hormone replacement therapy can be used in perimenopausal women with excessive menstrual bleeding (Rees and Barlow 1991).

Danazol

Danazol, a derivative of testosterone, causes endometrial atrophy by inhibiting release of the pituitary gonadotrophins and can reduce menstrual loss by as much as 50% (Chimbira et al 1980, Dockeray et al 1989). The use of danazol is limited by its androgenic side-effects, which include weight gain, acne, depression and other long-term metabolic sequelae, all of which reduce compliance. This drug is no longer recommended.

Gonadotropin-releasing hormone analogues

GnRH analogues act by causing pituitary downregulation and subsequent inhibition of cyclical ovarian activity, resulting in amenorrhoea. Their use is limited to less than 6 months because of problems related to the hypo-oestrogenic state, including hot flushes, dry vagina and decreased bone mineral density unless 'add-back' oestrogen/progestogen therapy is used concurrently. They are useful in a minority of women (Shaw and Fraser 1984) and also in those with fibroids before surgery.

Surgical treatment

Surgical treatments range from minor conservative procedures to hysterectomy (see Table 31.3). First- and second-generation ablation methods are a less invasive alternative to hysterectomy and are associated with high levels of satisfaction, but in a proportion, surgery may be required repeatedly, and there is some risk of perioperative morbidity. Hysterectomy is the definitive treatment to stop HMB, with satisfaction rates consistently greater than 90%. However, hysterectomy is a major operation with the potential for serious morbidity and, rarely, mortality. The inconvenience

to the patient and the cost to both the patient and the health services need to be balanced against the high levels of satisfaction that are reported after hysterectomy (Lethaby and Farquhar 2003).

Endometrial ablation techniques

Attempts at endometrial destruction in cases of heavy menstruation have been made by a variety of techniques. Early trials involved the intrauterine application of cytotoxic chemicals, intracavity radium, steam and cryosurgery. However, these were either ineffective or had unacceptable side-effects. They were also carried out blindly and, since the endometrium has remarkable powers of regeneration, any missed areas resulted in failure.

Endometrial ablation can be considered in a woman with HMB whose quality of life is affected to such an extent that she does not wish to preserve menstrual or reproductive function. This is suitable in woman with a normal uterus, and in those with small uterine fibroids (less than 3 cm) and a uterus no bigger than 10-week pregnancy size. Women wishing to have endometrial ablation should be provided with evidence-based information about its risks and benefits, and other available treatment options. Women must avoid pregnancy after endometrial ablation.

Hysteroscopic techniques (first generation) allow visualization of the uterine cavity, and enable the endometrium to be ablated under direct vision. Since regeneration of the endometrium occurs from the basal layer, it is essential to destroy all the endometrium. As the endometrial-myometrial border is irregular, the superficial layer of myometrium must also be included (Figure 31.8). There are a number of methods of achieving this, including removal of the tissue using a cutting loop, or coagulation or vaporization of the tissue using laser.

First-generation (hysteroscopic) ablation techniques (TCRE and rollerball endometrial ablation) are only appropriate if hysteroscopic myomectomy is to be included in the procedure.

Endometrial resection

The technique for TCRE is essentially similar to that of transurethral prostatectomy in men, and is performed through a continuous flow resectoscope. In this technique, a loop diathermy electrode is used to scrape out and remove the tissues through the cervix, and rollerball ablation uses an electrode with a movable ball or cylinder to coagulate and stop the bleeding tissues. It is important to destroy all the endometrium, otherwise regeneration will occur and the operation will fail. TCRE requires considerable skill if it is to be effective and safe. It is currently only used when hysteroscopic myomectomy is performed at the same time.

Laser ablation

Neodymium:yttrium-aluminium-garnet laser is optimal for intrauterine surgery, since it can be delivered along a flexible fibre through a liquid medium and the depth of tissue penetration can be controlled. The beam produces warming, coagulation, evaporation and carbonization. Tissue destruction typically occurs to a depth of 4–5 mm. Heat transmission through the myometrium is minimized by the continuous flow of cold irrigation fluid.

More recently, second-generation (non-hysteroscopic) ablation techniques are widely used because of a better safety profile compared with first-generation techniques. The second-generation techniques include: fluid-filled thermal balloon endometrial ablation, microwave endometrial ablation (MEA) and impedance-controlled bipolar radiofrequency ablation.

Thermal balloon ablation (Figure 31.9)

This involves the blind insertion of a balloon through the cervix, which is then filled with fluid until a pressure of 160–180 mmHg is reached. The fluid is then heated to 75–90°C (average 87°C). Endometrial destruction occurs over the next 8 min. The diameter of the insertion tube is very small and no cervical dilatation is required. This means that the procedure is particularly appropriate for women who are not suitable for or who do not wish to have a general anaesthetic. It is uncomfortable but pain relief can be improved by prior administration of a preparation such as diclofenac. Some sedation may be useful in certain instances. The success rate of this procedure appears to be similar to that for TCRE. One of the main advantages appears to be that pretreatment with a GnRH agonist is not required. Since the procedure is done in the outpatient setting in a number of units and has even been performed in general practice, it is likely to be a cheap and popular modality in the future. Outpatient thermal balloon ablation (Thermachoice III) can be performed in the majority of women, and is associated with similar overall pain scores but significantly less nausea, vomiting, need for antiemetics and less time spent in hospital compared with day-case Thermachoice III (Marsh et al 2007).

The procedure is effective and patient satisfaction is rated between good and excellent in more than 90% of cases. Complications of thermal balloon ablation include endometritis, urinary tract infection and haemorrhage, but all are uncommon (National Institute for Health and Clinical Excellence 2003).

Microwave endometrial ablation

MEA requires the insertion of a probe that emits microwaves into the uterus. The probe is then slowly moved across the fundus and down through the uterine cavity, destroying the

Figure 31.9 A thermal balloon inside the uterus (Thermachoice®, Gynecare, Edinburgh).

Table 31.3 Surgical and radiological treatment options for women whose quality of life is severely impacted
Provide information to the woman before her outpatient appointment.

Indication	Type of surgery	How it works	Will it impact on future fertility?	Other considerations	Potential unwanted outcomes experienced by some women*
Severe impact on quality of life + no desire to conceive + normal uterus +/- small fibroids (<3 cm diameter). Consider as first line only after full discussion of risks and benefits. Preferable to hysterectomy if uterus no bigger than 10-week pregnancy.	Endometrial ablation. Second-generation <ul style="list-style-type: none"> • Impedance-controlled bipolar radiofrequency • Balloon thermal • Microwave • Free fluid thermal • First generation • Rollerball • Transcervical resection of the endometrium 	It destroys the womb lining.	Yes	Discuss impact on fertility. Use second-generation technique in women with no structural or histological abnormality. Advise use of effective contraception following this procedure.	Common: vaginal discharge, increased period pain or cramping (even if no further bleeding), and need for additional surgery. Less common: infection. Rare: perforation (but very rare with second-generation techniques).
Fibroids (>3 cm diameter) + severe impact on quality of life. Consider as first line if there are other significant symptoms, pain or pressure. Recommended for women who want to retain uterus +/- avoid surgery.	Uterine artery embolization	Small particles are injected into the blood vessels that take blood to the uterus. The blood supply to the fibroids is blocked and this causes them to shrink.	Fertility is potentially retained	Discuss impact on fertility	Common: persistent vaginal discharge, postembolization syndrome – pain, nausea, vomiting and fever (not involving hospitalization). Less common: need for additional surgery, premature ovarian failure, particularly in women over 45 years of age, and haematoma. Rare: haemorrhage, non-target embolization causing tissue necrosis, infection causing septicæmia.
Fibroids (>3 cm diameter) + severe impact on quality of life. Recommended for women who want to retain uterus.	Hysteroscopic myomectomy	Surgical removal of the fibroids using hysteroscope.	Fertility is potentially retained	Discuss impact on fertility. Consider pretreatment with GnRH analogue. Following with a first-generation ablation technique is appropriate.	Less common: adhesions (which may lead to pain and/or impaired fertility), need for additional surgery, perforation, recurrence of fibroids and infection. Rare: haemorrhage
Fibroids (>3 cm diameter) + severe impact on quality of life.	Myomectomy	Surgical removal of the fibroids.	Fertility is potentially retained	Discuss impact on fertility. Consider pretreatment with GnRH analogue.	Less common: adhesions (which may lead to pain and/or impaired fertility), need for additional surgery, recurrence of fibroids and infection. Rare: haemorrhage

GnRH, gonadotrophin-releasing hormone; DVT, deep vein thrombosis.

*Common: one in 100 chance; less common: one in 1000 chance; rare: one in 10,000 chance; very rare: one in 100,000 chance.

endometrium. Provided that the probe is in the cavity of the uterus, this is a very safe procedure as the temperature rises as the endometrium is treated and the probe moved to another area. Randomized comparisons of this technique with TCRE suggest that it is equally effective; like TCRE, MEA also requires pretreatment with a GnRH agonist. In addition, since it requires dilatation of the cervix to 9 mm, it is unusual to perform this procedure under local anaesthetic. However, it is likely that smaller probes will be developed in order to achieve this result. The curative effect of MEA is similar to that of total hysterectomy, especially when preservation of the uterus and postoperative recovery is considered (Lin 2006).

These procedures are attractive alternatives to endometrial resection, although they are less valuable in the presence of uterine fibroids, particularly if the cavity is enlarged.

Success rates

There is little variation in success rates between the different methods. Overall, approximately 30% of women will be amenorrhoeic and a further 45–50% will have significantly decreased loss, giving a satisfaction rate of approximately 75% (Magos et al 1991, Scottish Hysteroscopy Audit Group 1995, Cooper et al 1999). Careful counselling is essential in that if a woman is keen to have amenorrhoea, this will not be the treatment of choice for her. Some women also experience relief from symptoms of dysmenorrhoea and premenstrual tension.

Complications

The most significant complications are those of uterine perforation and fluid absorption. Uterine perforation occurs in less than 1% of cases and is not usually associated with major problems, unless the device is activated within the abdominal cavity, when bowel or blood vessels may be damaged. Fluid absorption is rare since surgeons have become aware of the risk and stop the operation if absorption becomes excessive. Infection may also occur and most surgeons give prophylactic antibiotics routinely. MEA should be used with caution if there is a thin lower segment caesarean section scar.

Comparison of endometrial resection with hysterectomy

Endometrial resection was developed as an alternative to hysterectomy. However, it appears that the number of hysterectomies being performed is continuing to rise, suggesting that it is not serving this purpose. There have been a number of randomized comparisons between endometrial ablation and hysterectomy which show that satisfaction with both procedures is high (Pinion et al 1994). In addition, the operation can be performed on a day-case basis and recovery time is short, making it a cheap alternative to hysterectomy. However, it does appear that 20% of patients will require further surgical treatment, and there is still uncertainty regarding whether or not the number of failures will increase with time.

Endometrial resection is most likely to be successful in women over 40 years of age who have a normal-sized uterus and no intrauterine pathology. Its use in dysmenorrhoea is equivocal since it appears to make women worse in approximately 12% of cases, which may be due to the formation of haematometra. However, approximately 40% will improve so the presence of dysmenorrhoea is not an absolute con-

traindication. The menstrual cycle length will not be changed by the procedure, and hysterectomy may be an appropriate alternative in women with very irregular bleeding (Lewis 1994).

Hydrothermal ablation (fluid-filled thermal endometrial ablation)

Hydrothermal ablation is a procedure in which high-temperature water is used to destroy the lining of the uterus. It is used to treat abnormal uterine bleeding even when there are small submucous fibroids. The procedure is safe, effective and can be performed as a day-case procedure.

Novasure

The NovaSure system is safe and effective for the treatment of women with abnormal uterine bleeding. Endometrial pretreatment is not necessary, and the presence of blood in the uterine cavity during treatment is not a limiting factor. The procedure is quick, safe and simple. This minimally invasive procedure controls heavy bleeding by using energy to remove the lining of the uterus. The average treatment time is approximately 90 s, and the procedure only needs to be performed once to lighten or stop menses. NovaSure can be performed in the hospital or outpatient setting.

Without the side-effects of hormones or the risks of hysterectomy, NovaSure has a quick recovery time. Most women experience no pain after the procedure and can return to work the next day. With more than 500,000 patients treated to date, NovaSure is proven to be safe and successful. A clinical trial has shown that more than nine out of 10 women return to normal or lower than normal bleeding levels following treatment with NovaSure (Cooper et al 2002). For some women, their menses stopped completely. In a small percentage of patients, side-effects include cramping, nausea/vomiting, discharge and spotting.

Uterine artery embolization

This procedure is usually performed to treat fibroids associated with HMB, under local anaesthesia by an interventional radiologist. Particles are injected to block both uterine arteries. This shrinks the fibroids. This procedure is safe and there is symptomatic improvement in bleeding. There is no proven permanent effect on the uterus (National Institute for Health and Clinical Excellence 2007).

Uterine artery embolization (UAE), myomectomy or hysterectomy should be considered in HMB where large uterine fibroids (>3 cm diameter) are affecting the woman's quality of life. Women should be informed that UAE or myomectomy may potentially allow them to retain their fertility. MRI can be used, if required, prior to UAE or myomectomy to assess the position, size, number and vascularity of the fibroids. Three to four months of treatment with a GnRH analogue should be considered before myomectomy or hysterectomy where fibroids have enlarged or distorted the uterus. However, GnRH analogues should be stopped prior to UAE as they decrease the calibre of the vessels and make cannulation more difficult.

Hysterectomy

Hysterectomy is no longer recommended as a first-line treatment for HMB. Conservative surgery should be considered

prior to hysterectomy. Woman's expectations and the possible impact of hysterectomy on personal, psychological, sexual, family and social life should also be discussed in full and documented in the notes. Women should also be informed about the possible loss of ovarian function and its consequences (such as the need for hormone replacement therapy and its benefits and risks) even if the ovaries are preserved.

However, hysterectomy can be considered when other management options are contraindicated or have failed, or if the woman (being fully informed) requests it because she no longer wishes to retain her menstrual and reproductive function.

Hysterectomy, although an effective treatment for menstrual problems, is a major operation and is not without risk in terms of both mortality and morbidity. The major risks include intraoperative bleeding and damage to other abdominal organs, such as bladder, ureter or bowel. Complications are greater in the presence of fibroids.

The incidence of hysterectomy is gradually increasing in the Western world as a whole, but it varies considerably from one country to another, reflecting differences in the attitudes of both patients and gynaecologists rather than a variation in pathology. Women in Scotland have a 20% chance of losing their uterus before 60 years of age, whereas the figure is 50% in California.

In deciding the route of hysterectomy (vaginal, laparoscopic-assisted vaginal or abdominal), individual assessment is essential. Factors that influence this decision include: uterine size, mobility and descent; number, size and site of uterine fibroids; size, shape and prolapse of vaginal wall; history of previous surgery; and presence of comorbidities such as obesity, diabetes, hypertension or heart disease. The possibility of total and subtotal hysterectomy should also be discussed when abdominal hysterectomy is considered.

Healthy ovaries should not be removed at the time of hysterectomy. This should be discussed prior to the operation, and bilateral oophorectomy should only be performed with the express wish and consent of the woman. In the presence of a significant family history of breast or ovarian cancer, the woman needs appropriate genetic counselling. This is likely to help her make an informed decision about oophorectomy. In premenopausal women, especially those under 45 years of age, considering hysterectomy for HMB with other symptoms that may be related to ovarian dysfunction (e.g. premenstrual syndrome), a trial of ovarian suppression for 3–6 months should be used as a guide to the necessity for hysterectomy. Once oophorectomy is decided, the impact of this on the woman's well-being and the possible need for hormone replacement therapy should also be discussed.

Abdominal hysterectomy involves a laparotomy incision that is transverse or longitudinal. A vaginal hysterectomy involves an incision through the vaginal wall. For many surgeons, vaginal hysterectomy is the preferred method for women with some degree of uterine descent and where the uterus is not excessively large. Abdominal hysterectomy allows better visualization of the pelvic cavity should there be pathology or where difficulty is anticipated. Non-randomized studies indicate that the complication rate for abdominal hysterectomy is greater than that for vaginal hysterectomy, and women who have vaginal procedures are able

to go home sooner than women who have abdominal operations (Dicker et al 1982, Clinch 1994).

Recently, it has become possible to convert an abdominal hysterectomy to a vaginal hysterectomy using endoscopic techniques. The laparoscope allows visualization of the pelvic cavity, and all or part of the hysterectomy may be performed using specially designed laparoscopic instruments. A laparoscopic-assisted vaginal hysterectomy allows tissues accessible through the vagina to be ligated and the uterus to be removed by the vaginal route. This method facilitates the removal of ovaries and aids the operation when there is no uterine descent. It allows for dissection of adhesions and the treatment of pelvic pathology, such as endometriosis, prior to the hysterectomy. Published complication rates are low but recovery does not appear to be quicker than that following abdominal hysterectomy (Lumsden et al 2000), although the length of hospital stay is reduced (Boike et al 1993). Compared with abdominal hysterectomy, laparoscopic hysterectomy is associated with a higher rate of major complications, less postoperative pain and shorter hospital stay, but takes longer to perform (Boike et al 1993). The ovarian pedicles were only secured with laparoscopic sutures in 7% of cases, but this was associated with 25% of the complications. Abdominal laparoscopic hysterectomy is associated with a significantly higher risk of major complications and takes longer to perform than abdominal hysterectomy. Abdominal laparoscopic hysterectomy is, however, associated with less pain, quicker recovery and better short-term quality of life after surgery than abdominal hysterectomy. The cost-effectiveness of laparoscopic hysterectomy is finely balanced and is also influenced by the choice of reusable vs disposable equipment (Garry et al 2004).

Dysmenorrhoea

In young women, dysmenorrhoea is frequently the only menstrual abnormality. Prostaglandin synthetase inhibitors and the oral contraceptive pill are very effective (Anderson 1981), but in a minority of women, even in the absence of disease, these measures are insufficient. Calcium channel blockers (e.g. nifedipine) have been used in Scandinavia and are effective, although their use is limited by cardiovascular side-effects. Oxytocin/vasopressin receptor antagonists may become available when effective oral agents are developed.

In the past, presacral neurectomy was performed but this involved major abdominal surgery and was only effective in approximately 50% of cases. Recently, presacral neurectomy has been performed using intra-abdominal lasers. The long-term effect of this treatment has not been reported and it is only available in a few UK centres.

In older women where child bearing is completed, hysterectomy is often the solution since dysmenorrhoea in this group is frequently associated with other menstrual problems.

Conclusions

Menstrual dysfunction remains one of the most common reasons why women seek medical advice, yet the process of menstruation is poorly understood. Strategies to improve

the investigation and management of this problem are likely to arise from two directions. First, a thorough investigation of the medicosociological factors is required. Second, the role of vasoactive substances in the endometrium needs to be further investigated, as well as determination of the

factors that control endometrial proliferation. HMB affects work, family and social life. Investigations and management should be evidence based. When management options are discussed, there should be the flexibility to provide an acceptable solution for each individual woman.

KEY POINTS

1. HMB is the most common cause of iron-deficiency anaemia in Western women.
2. The menstrual cycle consists of proliferative, secretory and menstrual phases.
3. Menstruation is initiated by a withdrawal of progesterone and oestrogen support to the endometrium.
4. Menstrual loss is dependent upon the degree of platelet plug formation, vasoconstriction and endometrial repair. Abnormality in these mechanisms can result in menstrual dysfunction. Paracrine factors are also thought to play a role in the control of menstruation.
5. The mean menstrual blood loss is 37–43 ml per menses. Loss in excess of 80 ml per menses is considered to be HMB.
6. Abnormal menstrual loss may arise from pelvic pathology, clotting disorders, medical disorders or DUB.
7. DUB is defined as heavy or irregular bleeding in the absence of pelvic pathology, pregnancy or clotting disorder.
8. Anovulatory cycles may be associated with cystic glandular hyperplasia. This can occur in both older women and peripubertal girls, and may result in excessive menstrual loss.
9. Primary dysmenorrhoea occurs almost exclusively in ovulatory cycles, and prostaglandin secretion is strongly implicated in its aetiology.
10. Subjective and objective assessments of menstrual loss are poorly correlated. Medical treatment of HMB is less effective if the blood loss is within normal limits, unless there are other associated symptoms which are relieved.
11. Hysteroscopy and endometrial biopsy is more sensitive than endometrial curettage in the diagnosis of endometrial abnormality.
12. Hysterectomy is a very effective remedy for menstrual dysfunction but is associated with postoperative morbidity and mortality. It is the only treatment that is guaranteed to lead to amenorrhoea.
13. Laparoscopic-assisted vaginal hysterectomy allows conversion of an abdominal hysterectomy to a vaginal hysterectomy. It is associated with a shorter hospital stay, but the recovery time is similar to that following abdominal hysterectomy.
14. Endometrial ablation is a useful alternative to medical treatment or hysterectomy in cases of DUB and can be performed under local anaesthesia.
15. Medical treatment of HMB may result in good symptomatic relief and is safe but does not result in long-term cure.

INCIDENCE	473	TREATMENT METHODS	480
CLASSIFICATION AND PATHOPHYSIOLOGY	474	FUTURE DIRECTIONS	486
CLINICAL PRESENTATION	477	KEY POINTS	486

Introduction

Uterine fibroids are the most common type of tumour in women. Benign tumours, they arise from the uterine myometrium or, less commonly, from the cervix. The term 'fibroid' is inaccurate, as these tumours comprise smooth muscle cells contained within varying proportions of elastin, collagen and extracellular matrix proteins. They are more accurately termed 'leiomyomata' or 'myomas'.

There continues to be an appalling paucity of research on this tumour and its treatment. This is of particular concern given that it occurs in more than two-thirds of women at some stage of their lives, and is the leading indication for the most common major gynaecological operation in women — hysterectomy. The annual cost of inpatient surgery for fibroids is estimated to be \$US2.1 billion in the USA (Parker 2007), with additional indirect costs from outpatient treatment and lost time at work.

Incidence

The true incidence of uterine fibroids in the general female population is unknown. This is because most studies on fibroids have only included women with symptoms or women having treatments such as hysterectomy. Given that up to 50% of fibroids are asymptomatic (Buttram and Reiter 1981), the former approach can be expected to underestimate the true population incidence. However, studies of incidence based on histological examination of hysterectomy specimens may similarly overestimate the incidence of fibroids, as they concentrate the worst cases of menorrhagia where medical treatments have failed. Cramer and Patel (1990) found that 77% of hysterectomy specimens had fibroids on histology, although fibroids were only detected in 33% of patients clinically and 50% of patients by ultrasound examination.

The lifetime risk of a woman over 45 years of age developing fibroids is greater than 60%, with reported incidences in different studies varying from 30% to 70% for premenopausal women (Okolo 2008).

Aetiology

The precise aetiology of fibroids remains unknown. It is known that each fibroid is monoclonal, developing from a single cell. Electrophoresis patterns of glucose-6-phosphate dehydrogenase isoenzyme (A or B) demonstrated this in early studies (Townsend et al 1970). Later, polymerase chain reaction experiments confirmed monoclonality by the pattern of inactivation of the X-chromosome-linked phosphoglycerokinase gene (Hashimoto et al 1995). In the development of fibroid tumours, some form of initiation event must transform a normal myometrial cell into an abnormal 'founding' cell. Possible factors initiating this change include intrinsic myometrial abnormalities, elevated oestrogen receptors in the myometrium, hormonal changes and ischaemic injury (Parker 2007).

The initial transformation of the myometrial cell is likely to be accompanied in many cases by some form of cytogenetic or molecular alteration. Non-random chromosomal changes, such as translocations, duplications and deletions, can be identified in almost 50% of fibroids. The most frequent cytogenetic changes are translocations involving chromosomes 7, 12 and 14, and deletions in chromosome 7. The critical region affected in chromosome 7 appears to be on the long arm (7Q21–22). Several known genes are coded in this apparently critical region. These include genes for collagen type 1a 2, the MET proto-oncogene and the cytochrome P450 gene. There are rare instances of fibroids being due to mutations in a single gene, such as the mitochondrial enzyme, fumarate hydratase, involved in Krebs cycle and responsible for Reed's syndrome (multiple cutaneous and uterine leiomyoma syndrome). However, in the

vast majority of cases, uterine fibroids are not a single gene disorder. Once the fibroid tumour has been initiated, growth of the tumour occurs under the influence of sex steroid hormones (oestrogen and progesterone), peptide growth factors and the alteration of processes such as angiogenesis, apoptosis and extracellular matrix production.

It has long been known that fibroid growth is dependent on both oestrogen and progesterone. Fibroids only occur after the menarche, and they normally show a reduction in size after the menopause. They display reversible shrinkage after treatment with gonadotrophin-releasing hormone (GnRH) agonists. Although circulating serum oestradiol and progesterone levels are not altered in women with fibroids, fibroids have increased local oestrogen levels relative to the surrounding normal myometrium, partly due to increased fibroid expression of the aromatase enzyme (Parker 2007). They also have increased oestrogen receptor levels and increased responsiveness to oestrogen compared with normal myometrial cells. As for progesterone, the receptor levels have been shown to be increased in fibroids relative to the myometrium (Brandon et al 1993), and to upregulate the levels of some proteins which influence cell proliferation, such as the antiapoptotic protein Bcl-2 (Matsuo et al 1999). During the secretory phase of the menstrual cycle, when serum progesterone levels are at their peak, the highest mitotic activity is seen in fibroids. Similarly, high mitotic activity is seen during pregnancy. Treatment with the antiprogesterin, mifepristone, has been shown to cause a marked decrease in fibroid tumour volume.

A large number of growth factors are produced locally in uterine fibroids and the myometrium. Some of them are overexpressed in fibroids, partially due to an exaggerated response to oestrogen. Some of the growth factors that have been found to have a potential role in the promotion of fibroid growth include: transforming growth factor- β , epidermal growth factor, basic fibroblast factor, insulin-like growth factor, platelet-derived growth factor and vascular endothelial growth factor (VEGF). The differential effects of these growth factors on cell proliferation, angiogenesis, extracellular matrix production and apoptosis are due to a variety of mechanisms including altered receptor levels and signalling pathways. For a detailed review, see Fleischer et al (2008).

Epidemiology

Age is the most common risk factor for uterine fibroids (Marshall et al 1997), although many of the studies examining incidence are cross-sectional or retrospective, rather than prospective and longitudinal. Race has been identified as an epidemiological factor in fibroid development. Black women are three to five times more likely to have uterine fibroids than White, Asian or Hispanic women (Marshall et al 1997). In addition, the fibroids in Black women are larger, more numerous, more symptomatic and diagnosed at an earlier age.

There is evidence of hereditary factors influencing fibroid development, despite no specific gene being identified. The development of fibroids clusters in families, and 'familial' fibroids appear to be more likely to cause symptoms than 'non-familial' fibroids (Okolo 2008). Twin studies show an

increased incidence of fibroids in monozygotic twin pairs compared with dizygotic twin pairs.

Uterine fibroids are more common in nulliparous women, presumably due to the increased number of cycles over their premenopausal lifespan compared with parous women. Increasing parity decreases the incidence and number of fibroids. It is a myth that fibroids increase in size during pregnancy. In pregnancy, fibroids initially increase in size in the first trimester, but then decrease in size for the remaining two trimesters, with an overall volume that is either reduced or unchanged throughout the pregnancy (Hammoud et al 2006). Obesity, diabetes mellitus, polycystic ovary syndrome and hypertension all appear to be associated with an increased risk of uterine fibroids. In these conditions, a combination of insulin resistance, increased androgen levels and increased peripheral conversion of circulating androgens to oestrogen may alter the ovarian steroid hormonal stimulus to the fibroids. Smoking decreases the risk of uterine fibroids, presumably through a reduction in oestrogen levels.

The effects of exogenous sex steroid hormones on fibroid growth are particularly important as they comprise some of the most common treatments for menorrhagia, itself the most common symptom of uterine fibroids. Use of the combined oral contraceptive pill (COCP) has been associated with fibroid growth in some earlier studies (particularly older pill formulations with a higher oestrogen dosage), although the majority show no association or even a reduced risk of developing fibroids with COCP use. Therefore, fibroids are not a contraindication to the use of the COCP to treat menorrhagia. Both systemic and local administration of progestins to the uterus have been shown to be safe with fibroids. Depot medroxyprogesterone acetate injections reduce the risk of fibroids, and the levonorgestrel-containing intrauterine system (LNG-IUS; Mirena) reduces the overall volume of fibroid uteri. The LNG-IUS is also an effective treatment for menorrhagia associated with fibroids, although it is less effective than for dysfunctional uterine bleeding. In some patients, it may be difficult to insert the LNG-IUS due to cavity distortion by the fibroids. The effect of hormone therapy in postmenopausal women on fibroids has been reviewed by Ang et al (2001). They found that use of hormone therapy in women with fibroids caused continued fibroid growth, especially in the first 6 months of therapy, or at least a failure in normal postmenopausal regression. However, this did not correspond to an increase in symptoms.

Classification and Pathophysiology

Macroscopic appearance

Fibroids have a characteristically firm fibrous texture, from which the clinical term 'fibroid' is presumably derived. They frequently become calcified; rarely, they become ossified so that they are rock hard. Fibroids are round or oval-shaped tumours with a characteristic white whorled appearance on cross-section. They may be single but are more commonly multiple, present in varying sizes and in different sites (Figure 32.1). Tiny 'seedling' fibroids are commonly seen in association with larger tumours, possibly accounting for the high recurrence rate after surgical removal at myomectomy.

Surgical removal of over 120 individual fibroids from a single patient has been recorded in the literature!

Clinical classification

Subserosal fibroids

Subserosal fibroids project outwards from the uterine surface, covered with peritoneum, and may reach a very large size. Greater than 50% of the fibroid mass must project beyond the myometrium for the fibroid to be classified as subserosal. Many subserosal fibroids are pedunculated (Figure 32.2), making torsion a potential, although rare, complication. Sessile subserosal fibroids projecting from the fundal region may adhere to omentum or bowel, particularly if there has been coincidental inflammatory disease. Fibroids rarely become attached to the omentum; if they develop an alternative blood supply, they may become separated from the uterus, forming a so-called 'parasitic' fibroid. Subserosal fibroids arising from the lateral uterine wall may lie between the layers of the broad ligament where large tumours may displace the ureters, or bulge between the layers of the sigmoid mesocolon. Broad ligament fibroids arising from

the lateral uterine wall differ from true broad ligament fibroids, which have no attachment to the uterus but have their origin in smooth muscle fibres within the broad ligament; for example, from the round ligament, ovarian ligament or perivascular connective tissue.

Intramural fibroids

Intramural fibroids lie within the wall of the uterus. A strict definition requires more than 50% of the fibroid mass to lie within the myometrial layer of the uterus, although smaller percentages of the tumour mass may project either into the uterine cavity or out from the serosal layer. They are separated from the adjacent normal myometrium by a thin layer of connective tissue which forms the so-called 'pseudocapsule' or 'false capsule'. This pseudocapsule is of great help when performing a myomectomy, as it provides a plane of easy cleavage to enucleate the fibroid tumour but leave the remainder of the uterus.

Submucosal fibroids

Submucosal fibroids are less common, comprising approximately 5% of all leiomyomata. By definition, more than 50% of the fibroid mass projects into the uterine cavity and is covered by endometrium. Submucosal fibroids may cause abnormal uterine bleeding and infertility. Uterine enlargement is not usually evident unless other fibroids are also present. Submucous fibroids are regarded as suitable for hysteroscopic resection. Pedunculated submucous fibroids on a long stalk may prolapse through the cervix (Figure 32.3), where they may cause intermenstrual bleeding or become ulcerated and infected.

Figure 32.1 Uterus enlarged by multiple fibroids. The patient presented at 43 years with menorrhagia; she had a 13-year history of primary infertility. Septate vagina and double cervix (marked with rods).

Figure 32.2 Multiple subserous fibroids, some pedunculated. Specimen width 350 mm.

Figure 32.3 Submucous fibroid protruding through cervix. The patient, aged 44 years, presented with a 3-week history of continuous bleeding; haemoglobin level was 6.9 g/dl.

Cervical fibroids

Cervical fibroids are relatively uncommon but give rise to the greatest surgical difficulty by virtue of their relative inaccessibility and close proximity to the bladder and ureters. Enlargement causes upward displacement of the uterus, and the fibroid may become impacted in the pelvis, causing urinary retention and ureteric obstruction. During labour, a cervical fibroid may prevent descent of the fetal head, resulting in obstructed labour; if on the anterior surface of the uterus, a cervical fibroid may complicate caesarean section surgery.

Vascular supply

Perfusion studies with injections of ^{133}Xe radiocontrast and gadolinium-enhancement contrast material during magnetic resonance imaging (MRI) show reduced blood flow through fibroids compared with myometrium, but increased blood flow in a compressed rim around the fibroid. Immunohistochemical studies of the microvascular density of fibroids demonstrate reduced vessel area staining in fibroids compared with the myometrium (Casey et al 2000), and with the difference increasing after the menopause (Weston et al 2005); this is probably due to relatively faster collapse of the myometrial cellular and extracellular matrix volume relative to that of the fibroid. Electron microscopy of corrosion vessel casts of fibroids performed by Walocha et al (2003) shed even greater insight into the vasculature of fibroids. A single larger artery usually provides the major blood supply to the fibroid, sending small nutrient arteries to penetrate the capsule. The vasculature of fibroids is reduced compared with the surrounding myometrium, but is most markedly reduced in smaller fibroids, with the only area of greater vascularity than the myometrium being the compressed rim of perifibroid tissue around the periphery of larger fibroids. Walocha et al (2003) proposed an initial regression of the vasculature within smaller fibroids, followed by an intense proangiogenic response, whereby the vascular rim around the fibroid acts as the source for neovascularization of the growing fibroid.

The relative avascularity of the fibroid core appears to be at odds with the finding of increased VEGF in fibroids com-

pared with the myometrium. However, the VEGF within the interior of the fibroid may be trapped in a biologically inactive fashion within the expanded extracellular matrix of the fibroid. A gene expression microarray experiment performed by Weston et al (2003) specifically targeting angiogenesis-related genes found a reduced level of two angiogenesis promoters (CTGF and CYR61) and increased expression of collagen IVa 2; a precursor for the angiogenesis inhibitor, canstatin. This triad of gene expression differences may, in part, explain the relatively avascular fibroid tissue.

Microscopic appearance

Microscopically, fibroids are composed of smooth muscle cell bundles, also arranged in whorl-like patterns (Figure 32.4A), admixed with a variable amount of connective tissue, although the latter rarely predominates. The relatively poor blood supply to individual fibroids may result in degenerative changes, particularly within large tumours. Hyaline degeneration (Figure 32.4B) is the most common, resulting in a smoother and more homogeneous consistency, which may become cystic if liquefaction occurs. Much more rarely, fatty change may develop. This is distinct from the true lipoma of the uterus, which is extremely uncommon. Calcification (Figure 32.5) is a later consequence of degeneration secondary to circulatory impairment. It characteristically occurs after the menopause, although it may occur earlier in subserosal fibroids with narrow pedicles.

There are a number of recognized histological variants of the usual microscopic appearance of uterine leiomyomata. The term 'cellular leiomyoma' is used when the density of the smooth muscle cells is significantly greater than usual, but there are no other atypical features such as increased mitotic activity or abnormal mitoses. Some pathologists use the term 'neurilemmoma-like leiomyoma' when there is striking lining-up or palisading of the tumour nuclei. This resembles nerve sheath tumours. Sometimes, fibroids are composed of polygonal cells rather than spindle cells. This type of nuclear pleomorphism is associated with giant cell formation; such tumours are called 'symplasmic', 'bizarre' or 'atypical' leiomyomas.

One differential diagnosis of uterine fibroids is that of adenomyosis, which may have a similar macroscopic appearance to uterine fibroids. However, in adenomyosis, there is no clear demarcation from the adjacent normal tissue. Leiomyosarcoma is a malignant tumour of the smooth muscle of the uterus. The macroscopic appearance of leiomyosarcoma shows an irregular invasive margin and a variegated cut surface. The microscopic appearance of leiomyosarcoma shows high cellularity, nuclear pleomorphism, a high mitotic rate with abnormal mitoses and areas of necrosis with infiltrating margins. Typically, the number of mitoses per 10 high-power fields in leiomyosarcoma is greater than 10, in contrast to standard leiomyoma where the number of mitoses per 10 high-power fields is less than five.

Finally, there are rare groups of uterine tumours with histological features intermediate between fibroids and leiomyosarcomas. These are termed 'smooth muscle tumours of uncertain malignant potential'. Other rare tumours include endometrial stromal nodule, diffuse leiomyomatosis and endometrial stromal sarcoma.

Crow et al (1995) examined the microscopic appearance of uterine fibroids after treatment with GnRH agonists. They found considerable variation between fibroids after a course of treatment and subsequent myomectomy or hysterectomy. Decreases in the extracellular matrix, in particular, cause extreme crowding of tumour nuclei, resulting in a densely cellular appearance of such fibroids on microscopic examination. For the inexperienced pathologist, this will be worrying in terms of possible malignancy. There should not, however, be mitotic activity, cytological atypia or coagulative necrosis.

Clinical Presentation

Abnormal bleeding/menorrhagia

The proportion of uterine fibroids causing abnormal uterine bleeding — menorrhagia being the most common abnormal pattern observed — is uncertain but is usually quoted as 30–50%. The exact mechanism by which fibroids cause menorrhagia is unknown. The many theories include: increase in endometrial surface area (Figure 32.6), increased vascularity of the uterus, vascular congestion due to fibroid compression of the myometrial venous drainage, abnormal uterine contractility, dysregulation of growth factors causing disordered angiogenesis of the uterine vasculature, and ulceration of the endometrial layer overlying submucous fibroids.

As fibroids are so common, and so often asymptomatic, menorrhagia in a woman with uterine fibroids should not automatically be ascribed to the fibroids themselves. Other possible aetiologies for menorrhagia should always be considered and excluded, including coagulopathies such as von Willebrand's disease (Munro and Lukes 2005). In a study of self-reported bleeding patterns by 878 women (aged 35–49 years) screened for the presence and size of myomas, Wegienka et al (2003) reported findings on the association between fibroids and bleeding pattern. Of women with fibroids, 46% reported 'gushing' episodes during their periods, compared with 28% without fibroids. Gushing episodes and length of periods were related to the size of the

Figure 32.6 Hysterosalpingogram showing enlargement of uterine cavity and filling defect from intramural fibroid. Extensive endometriosis had complicated laparoscopic sterilization (hence the two clips on the left tube). Image courtesy of Dr B. Muir.

myomas, but not to their number or location. The worst bleeding was found with fibroids over 5 cm in diameter, with women using three more pads or tampons on heavy bleeding days than women with smaller fibroids.

Pelvic pain and pressure symptoms

Fibroids do not usually give rise to pain. In a cohort study of 635 non-care-seeking women, symptoms of dyspareunia, dysmenorrhoea and non-cyclic pelvic pain were examined for their association with the presence and size of uterine fibroids (Lippman et al 2003). The 96 women with fibroids had only a slight increase in non-cyclic pain or dyspareunia, but no increase in dysmenorrhoea, and no relationship was found between the size or total volume of fibroids and pain symptoms. Where fibroids are associated with pain or abdominal discomfort, it is usually described as 'pressure' or a 'dragging' sensation. It is surprising that even in the presence of multiple fibroids, menstruation may be painless.

Exceptionally, the presentation of fibroids may be acute on account of torsion of a fibroid on a narrow pedicle, or degeneration. Attempted expulsion of a large submucous fibroid through the cervix causes uterine cramp associated with bleeding, and may be mistaken for spontaneous abortion, particularly with the finding of a dilated cervix and a protruding mass. This situation has been described as a complication of treatment with GnRH analogues. Rarely, it can result in uterine inversion. Torsion or painful degeneration presents with an acute abdomen, and is commonly confused with complications of ovarian neoplasia. Distinction between these conditions is particularly important in pregnancy complicated by red degeneration of a fibroid, in order to avoid subjecting the woman to unnecessary laparotomy.

The location and size of fibroids determines symptoms from pressure on adjacent organs. A posterior wall fibroid can cause lower back pain, or constipation and tenesmus if the rectosigmoid is compressed. Anterior wall fibroids compressing the bladder may cause urinary frequency, nocturia

Figure 32.7 Cervical fibroid growing anteriorly in the supravaginal cervix. Presentation was with frequency of micturition followed by acute urinary retention.

and urgency in some women. It has been shown that reduction in size of such fibroids after either GnRH agonists or uterine artery embolization (UAE) causes a decrease in associated urinary symptoms (Parker 2007). Cervical fibroids causing compression of the bladder outlet may present with acute retention of urine (Figure 32.7), although this is rare.

Reproductive outcomes

Infertility/miscarriage

Fibroids are associated with infertility, although it has been estimated that fibroids are only responsible for 2–3% of cases (Buttram and Reiter 1981). Increasing maternal age increases the likelihood of both fibroids and infertility, making it a possible confounding factor. It is not known why fibroids increase infertility. Hypothetical mechanisms include interference with embryo implantation or sperm/embryo transport due to distortion of the cavity or tubal ostium, and an altered uterine environment due to increased local oestrogen levels or a local inflammatory effect. Embryo implantation may be reduced due to endometrial oedema, atrophy or ulceration, which in turn could be due to either the pressure effects of the uterine fibroid or its effects on the local blood supply. There have been series indicating post-operative pregnancy rates of 50–60% in women after myomectomy, but these studies have usually been uncontrolled or poorly controlled.

The effect of fibroids on assisted reproductive technology (ART) has been the subject of many studies, often with conflicting results. In an excellent systematic literature review, Klatsky et al (2008) summarized the evidence for the effects of fibroids on the results of in-vitro fertilization (IVF). It is generally accepted that subserosal fibroids, with more than 50% of their mass outside the myometrial border, are unlikely to have an adverse effect on IVF outcomes or

to increase the risk of miscarriage. This was confirmed by Eldar-Geva et al (1998), with subserosal fibroids not influencing treatment outcome after ART. However, in a series of 88 patients, treatment outcome after ART was impaired with either submucosal fibroids or intramural fibroids, even without uterine cavity distortion. Established wisdom is that submucosal fibroids should undergo hysteroscopic resection prior to ART. Submucosal fibroids, if not removed, are associated with an overall 70% reduction in pregnancy rate and 72% reduction in implantation rate compared with controls (Klatsky et al 2008), as well as an approximate doubling of the risk of miscarriage. Intramural fibroids are where controversy begins. Surgery to remove them is more risky and involved than that for submucosal fibroids, while the evidence is for a smaller and less consistent effect. Some authors (Khaund and Lumsden 2008) believe that intramural fibroids have an adverse effect on fertility where they cause distortion of the uterine cavity, and should be removed if they do so. Others (Klatsky et al 2008), citing disparity of study results, possible biases including publication bias and the small effect, feel that more prospective studies of intramural fibroids are required before a strong recommendation on desired treatment can be given. Their cumulative results from 18 controlled studies showed a slight decrease in implantation rate (18% vs 22%) and clinical pregnancy rate (37% vs 41%), and an increase in miscarriage rate (8% vs 15%) associated with intramural fibroids.

Pregnancy complications

The best-available evidence points to an increased risk of caesarean section delivery with fibroids, mainly due to malpresentation of the fetus. Incoordinate uterine action and labour dystocia were increased in at least one study on pregnant women with fibroids, but fibroids are not a contraindication to a trial of labour. The results for placenta praevia and placental abruption are conflicting, with some studies showing an increased risk and other studies showing no increased risk. Preterm labour and delivery are more common with uterine fibroids (odds ratio 1.5–1.9). At least four studies showed an increased risk of postpartum haemorrhage with uterine fibroids (Klatsky et al 2008). Despite the considerable evidence of adverse pregnancy outcomes with uterine fibroids, it should be noted that the data are often conflicting in different studies. Also, confounding factors such as advanced maternal age, and ascertainment bias from increased use of ultrasound in complicated pregnancies, need to be considered.

In approximately 5% of pregnant women with fibroids, the fibroids undergo red degeneration. This is a form of coagulative necrosis resulting in a haemorrhagic, meaty, cut surface and areas of cystic degeneration or mucinous change. One hypothesis is that changes in orientation of the myoma to its vascular supply during uterine growth cause obstruction of the vascular supply and ischaemic necrosis of the fibroid tissue (Parker 2007). Red degeneration causes severe abdominal pain and mild fever, and often requires a short hospital stay and treatment with non-steroidal anti-inflammatory drugs, such as ibuprofen. A similar clinical presentation can occur after GnRH agonist treatment or uterine artery embolisation UAE.

Malignant transformation in fibroids: where is the evidence?

For the 'worried well', the diagnosis of a uterine fibroid naturally raises the issue 'Can it become cancer, doctor?'. Some women continue to have a hysterectomy or a myomectomy 'just in case' the uterine fibroid grows into a uterine sarcoma. Gard et al (1999) reviewed uterine leiomyosarcomas in Australia, conducting a retrospective survey of major teaching hospitals in Sydney and Melbourne. They identified 49 patients treated over a 28-year period, equating to approximately one leiomyosarcoma of the uterus per million Australian women per year. There is considerable doubt regarding whether or not a myomectomy would be protective in any case, as most leiomyosarcomas are believed to arise *de novo*, unrelated to existing benign fibroids. Malignant transformation of fibroids is believed to be exceedingly rare; genetic differences between uterine fibroids and leiomyosarcomas point to distinct origins. Given that leiomyosarcomas can also arise outside the uterus, even a hysterectomy may not be completely protective of this rare tumour. Removing asymptomatic fibroids from women on this basis cannot be justified. Until proven otherwise, sarcomatous 'change' in a fibroid is a myth. Even rapid myoma growth almost never indicates a uterine sarcoma. No cases of sarcoma were found in a study of 198 fibroid uteri with an increase in size greater than 6 weeks over a 1-year period (Parker et al 1994).

There are many types of uterine sarcoma, all differing in their biological behaviour. The clinical benefits of oophorectomy, lymphadenectomy and cytotoxic chemotherapy remain controversial for these various types of leiomyosarcoma, not least because they are rare, even in the clinical experience of gynaecological oncologists.

Investigations for Uterine Fibroids

The investigations outlined below are those intended to diagnose the condition. However, required investigations will vary depending on the presenting problem. With menorrhagia, for example, a full blood examination should be performed to look for anaemia. Also, if surgery is anticipated, investigations to establish fitness for surgery should be performed.

Ultrasound

Ultrasound should always be used to confirm or clarify the nature of a pelvic mass. Both the transabdominal and transvaginal route should be taken in examining possible fibroids. Larger fibroid uteri may only be fully visible via the abdominal route, but smaller lesions and submucosal fibroids may be better visualized via the vagina. Ultrasound is rapid, inexpensive and uses no ionizing radiation, making it the undisputed first-line imaging investigation for fibroids. Even in relatively unskilled hands, it will diagnose pregnancy and differentiate between cystic and solid lesions (Figure 32.8). With appropriate training and experience, the site and nature of a pelvic mass may be predicted with accuracy in over 80% of cases. Fibroids appear as an enlarged uterus with patchy echogenicity. Serial ultrasound examination is of value in

Figure 32.8 Ultrasound appearance of uterus enlarged by multiple fibroids, showing patchy echogenicity.
Image courtesy of Dr B. Muir.

monitoring fibroid size during medical or conservative treatment. The volume of individual fibroids or of the whole uterus can be calculated by measuring the diameter in three planes at right angles and using the formula $\frac{4}{3}\pi r^3$, where r is the radius.

Sonohysterography, where the use of ultrasound is accompanied by the instillation of sterile saline into the uterine cavity via a balloon catheter, enables improved delineation of intrauterine pathology, such as submucosal fibroids. It also allows the diagnosis of endometrial polyps and intrauterine adhesions. Even large submucosal fibroids, up to 4–5 cm in diameter, can then be considered for hystero-

scopic resection, especially if more than 50% of the volume of the tumour is projecting into the uterine cavity.

Magnetic resonance imaging

While it is an excellent imaging modality for mapping the precise location and size of uterine fibroids, the use of MRI is limited by its expense and availability. While the accuracy of ultrasound is operator dependent, MRI has an overall low interobserver variability. It allows the diagnosis of adenomyosis, a common differential diagnosis of uterine fibroids. Nonetheless, until the cost and access to this imaging modality improve, it will not be a routine investigation for the diagnosis of myomas.

Hysteroscopy

Hysteroscopy as an investigational procedure is very effective for the diagnosis of submucosal fibroids. Diagnosis and treatment can occur at the same time if the appropriate equipment (a resecting hysteroscope) is available. The use of hysteroscopy allows endometrial sampling to be performed at the same time to diagnose coexisting endometrial pathology (endometrial hyperplasia, cancer or polyps). However, it is an invasive procedure, with both surgical and anaesthetic risks that are not incurred by the use of ultrasound alone.

Laparoscopy

Diagnostic laparoscopy can be of clinical value if the uterus is not larger than a 12-week gestation size and there is associated infertility or pelvic pain. It may reveal the presence of coincidental endometriosis, pelvic adhesions or other tubal pathology. Laparoscopy will also differentiate between a pedunculated fibroid and an ovarian neoplasm if there is an individual patient where this diagnosis is unclear on the basis of clinical and ultrasound findings.

Treatment Methods

Expectant management

At least 50% of fibroids are asymptomatic, and provided that their nature can be determined with reasonable certainty, active treatment is unnecessary. While traditionally, surgical removal has been advocated when the uterine size exceeds that of a 12-week pregnancy, this policy has been challenged (Reiter et al 1992). The mere presence of a fibroid uterus carries no long-term detrimental effects; spontaneous regression of the fibroid(s) after the menopause may be anticipated. Sarcomatous change in fibroids if they are left *in situ* is a myth.

Medical management

There are two main objectives in the medical treatment of uterine fibroids: relief of symptoms associated with fibroids, and reduction in fibroid size. No medical treatment has been shown to cause complete regression of fibroids. Where medical treatments cause fibroid shrinkage, there is a high rate of regrowth following cessation of treatment, as well as

a recurrence of symptoms. This has severely limited the use of medical treatment for fibroids.

Medical treatment of menorrhagia associated with fibroids

Since fibroids are often associated with menorrhagia, the effect of medical treatments for menorrhagia, with respect to both symptoms and fibroid growth, is important. As mentioned above, oral contraceptive pills with a high dose of oestrogen have been reported to cause fibroid growth. Later studies with current lower oestrogen-containing pills have shown either no change or a reduction in size. Similarly, the de-novo incidence of fibroids in users of the oral contraceptive pill appears to be decreased or no different compared with controls. Thus, the use of the oral contraceptive pill to treat menorrhagia in the setting of a fibroid uterus is not contraindicated (Benagiano and Primiero 2006).

There have been very few studies examining the effect of non-hormonal treatments for menorrhagia in women with fibroids. There have been no published randomized-controlled trials examining the effect of tranexamic acid on menstrual blood flow in women with fibroids. Non-steroidal anti-inflammatory drugs, such as ibuprofen and naproxen, have been shown to be ineffective in treating fibroid-related menorrhagia, despite their effectiveness for idiopathic menorrhagia and dysfunctional uterine bleeding. While not addressing the cause of the anaemia, iron tablets, often in combination with vitamin C tablets to aid absorption, are an effective treatment for mild-to-moderate iron-deficiency anaemia associated with menorrhagia.

The LNG-IUS is highly effective for the treatment of menorrhagia. It is also effective for the treatment of menorrhagia associated with fibroids, although less effective than for dysfunctional uterine bleeding. There is an increased risk of expulsion or failed insertion with fibroids, particularly where they cause cavity distortion. Regarding the effect of the LNG-IUS on fibroid growth, the data are conflicting (Benagiano and Primiero 2006). Despite initial reports of regression in the size of fibroids, subsequent studies have shown no decrease in size.

Gonadotrophin-releasing hormone analogues

GnRH analogues reduce the size of uterine fibroids significantly, thus relieving pressure symptoms as well as menorrhagia. However, their use as a primary treatment for fibroids is hampered by the rapid and high rate of recurrence after cessation of therapy, as well as menopausal symptoms and bone demineralization with long-term use. Due to these problems, as well as their high cost, their use is now largely restricted to an adjunct or pretreatment to surgery.

GnRH agonists should be commenced in the mid-luteal phase of the ovarian cycle for the most rapid pituitary down-regulation. Bleeding in response to oestrogen withdrawal occurs during the initial treatment cycle, but amenorrhoea is usual thereafter. Gonadal suppression results in vasomotor symptoms and vaginal dryness. Uterine volume assessed by MRI reduces by 35% after 3 months, and 50% after 6 months, with little change thereafter. The effects of treatment only persist for the duration of administration. The optimal duration of presurgical treatment with GnRH agonists is 3

months, which will also correct associated anaemia. Appropriate doses of currently available GnRH agonists include goserelin 3.6 mg (Zoladex) or leuprolin 3.75 mg (Lupron) by monthly subcutaneous depot insertion, and buserelin 900–1200 µg or nafarelin 800 µg (Synarel) intranasal sprays in divided doses. Therapy should be initiated in the mid-luteal phase of the cycle with no sexual intercourse that month in order to avoid accidental initiation during early pregnancy. Compliance may be a problem with the nasal spray; as erratic usage may result in stimulation rather than suppression of pituitary–ovarian function, hence administration by subcutaneous depot is preferable.

For women nearing the menopause who are particularly keen to avoid surgery, the use of GnRH analogues as a stand-alone therapy, with 'add-back' therapy to reduce menopausal symptoms, has been proposed as a viable alternative to surgical treatment. Low-dose oestrogen/progesterone combinations, oral progesterone alone and tibolone have been used to ameliorate the vasomotor symptoms associated with GnRH agonist gonadal suppression, but without compromising fibroid shrinkage (Sankaran and Manyonda 2008).

Other medical treatments

Danzol cannot be recommended for long-term treatment for fibroids because of marked androgenic activity. After short-term treatment, there is rapid return of size and symptoms, as with GnRH analogues. Selective oestrogen receptor modulators have no proven role in the medical treatment of fibroids in humans, despite their success in animal models. Aromatase inhibitors such as anastrozole are only effective for the treatment of fibroids in postmenopausal women. Given that their fibroids are regressing due to the naturally hypo-oestrogenic state of menopause, the number of patients for whom aromatase inhibitors would be a useful treatment is extremely small. GnRH antagonists have been shown to have a similar effect as GnRH agonists in the treatment of fibroids, although with faster effects. However, GnRH antagonists are more costly than agonists at present, limiting their feasibility as a treatment for most patients.

Antiprogesterone treatment

The use of antiprogesterone RU486, mifepristone, has been reported to reduce fibroid size and fibroid-related symptoms, making it a potentially promising new medical treatment. However, there have been varying reports of increased incidence of endometrial hyperplasia following prolonged use of mifepristone, due to its antiprogesterone effects on the endometrium (Tropeano et al 2008). Recurrence rates after cessation of therapy are likely to be high, and risk to any potential pregnancies makes its use for women with infertility particularly troublesome. Further studies are required with larger numbers of patients over longer periods to reliably determine the long-term efficacy and safety of treatment.

Asoprisnil, a selective progesterone receptor modulator (SPRM) with mixed agonist/antagonist effects, has also been used to treat fibroids. It inhibits the proliferation of endometrial cells, unlike mifepristone, theoretically reducing the risk of endometrial hyperplasia with treatment. Only one

randomized, double-blind, placebo-controlled trial of asoprisnil for the treatment of fibroids has been reported (Chwalisz et al 2007). It found that asoprisnil treatment for 3 months reduced fibroid-related symptoms and size in a dose-dependent manner, without hypo-oestrogenic symptoms or endometrial hyperplasia. Clearly, longer-term and larger trials are needed, but the initial results are promising. Other SPRMs are likely to be trialled for the treatment of fibroids over the next few years.

Hysterectomy

Management of symptomatic uterine fibroids has traditionally been surgical. Despite the existence of newer, less invasive techniques, their lack of availability in most centres means that, for most women, the decision for treatment continues to be between hysterectomy or myomectomy. The decision to perform a hysterectomy should not be undertaken without due consideration of the alternatives. For women who wish to preserve their reproductive function, myomectomy or medical treatment must be considered. Hysterectomy is clearly an effective treatment for fibroids, but it carries considerable risk of major complications (up to 10% with a large fibroid uterus).

The route selected for hysterectomy will depend on the size of the uterus, the situation of the fibroids and the history of any previous surgical procedures. Abdominal hysterectomy with ovarian conservation (Figure 32.9) will be the procedure of choice where fibroids are very large. For gynaecologists who favour vaginal hysterectomy, consideration should be given to preoperative shrinkage with a GnRH agonist, as described below. Similarly, a reduction in volume and vascularity may facilitate removal of a very large uterus by the abdominal route. Abdominal hysterectomy is rendered difficult in the presence of large fibroids arising from the cervix or situated in the broad ligament. It is also more complicated if there are adhesions from previous myomectomies, or from associated endometriosis or pelvic inflam-

matory disease. Difficult access to the pelvis during hysterectomy for large fibroids will be rendered easier by prior enucleation of the fibroids. The ureters may be vulnerable during an operation to remove a broad ligament fibroid, and their pathway must always be identified. Regardless of the direction of displacement, they are always extracapsular. In the case of a large cervical fibroid, an alternative approach is hemisection of the uterus, followed by enucleation of the fibroid in order to gain access to the uterine arteries and cervix. These techniques are described in detail elsewhere (Monaghan 1986).

The increasing popularity of minimal access surgery has led to the use of laparoscopic-assisted methods of vaginal hysterectomy in women with large fibroids, sometimes following prior shrinkage with a GnRH agonist. Even a large fibroid uterus can be removed via the laparoscopic method, using a morcellator to remove the fibroid and/or uterus piecemeal. However, the place of laparoscopic-assisted or total laparoscopic hysterectomy in the treatment of uterine fibroids remains unclear due to the lack of comparative studies with more traditional surgical methods.

Abdominal myomectomy

Removal of individual fibroids was first reported in the middle of the 19th Century, although current surgical techniques are largely attributable to Victor Bonney who described a personal series of 403 cases. The main indication for myomectomy is a woman with symptomatic fibroids who wishes to retain her uterus.

Unless the fibroid uterus is exceptionally large (greater than a 20-week gestation uterus), a Pfannenstiel or lower transverse incision should provide adequate access, as the uterus can usually be mobilized through the wound with the assistance of a myoma screw. If it is a repeat myomectomy, however, bowel adhesions are common and may necessitate a vertical midline incision. The uterus with the fibroid(s) is exteriorized after careful inspection of the pelvis for coexistent pathology. The uterine incision is made with either cold knife or cutting diathermy, the fibroid(s) grasped with either a myoma screw or tenaculum, and the fibroid enucleated either with finger or scissors around the usually clear tissue plane of the pseudocapsule. Every effort should be made to remove all palpable fibroids. After removal, the cavities left behind should be closed meticulously with figure-8 sutures (the authors usually use absorbable Vicryl sutures) to prevent haematoma collection, and the serosal layer should be closed with a continuous subserosal suture.

Complications

The two major problems associated with abdominal myomectomy are intraoperative blood loss (which can be severe and may necessitate a hysterectomy to control bleeding in 1–2% of patients) and postoperative adhesion formation. The risk of adhesions is increased with posterior and multiple uterine incisions. They are usually a consequence of difficulties with haemostasis and oozing from incision lines. Adhesions after incisions on the posterior wall are potentially more serious because of involvement of the uterine tubes and ovaries. To minimize adhesion formation, as many fibroids as possible should be removed through a

Figure 32.9 Hysterectomy specimen from uterus enlarged to 16-week gestation size by single intramural fibroid and several small seedling fibroids. Uterine volume was 575 ml.

Figure 32.10 Removal of subserous, intramural, submucous and posteriorly located intramural fibroids through a single anterior incision. Reproduced with permission of the American Society for Reproductive Medicine, formerly the American Fertility Society.

single incision (Figure 32.10), preferably at the fundus or anterior uterine wall. Some authorities recommend removal of posterior wall fibroids via the uterine cavity through an incision on the anterior abdominal wall, although this causes a deliberate breach of the uterine cavity and entails a risk of intrauterine adhesions. Bonney (Monaghan 1986) described a 'hood' method of closure of the cavity left after enucleation of a large single posterior tumour (Figure 32.11), suturing the redundant flap of serosal-covered myometrium over the fundus and low down on to the anterior abdominal wall to avoid adhesion formation. Keeping tissues moist, using wet packs to displace the bowel and minimal tissue handling is thought to reduce adhesions. The use of barrier agents, such as Interceed, Seprafilm and Gore-Tex, to reduce adhesions has been the subject of a recent Cochrane review (Ahmad et al 2008). While the use of Interceed does reduce postoperative adhesion formation after surgery, there is insufficient evidence to show that the reduced adhesion rates correspond with increased fertility and pregnancy rates.

Both mechanical and medical methods have been described to reduce intraoperative blood loss. Preoperative treatment with GnRH analogues for at least 3 months prior to either hysterectomy or myomectomy has been shown to

increase both preoperative and postoperative haemoglobin and haematocrit (Lethaby et al 2000). This also reduced the size of the fibroids by approximately 50%, and reduced pelvic symptoms, operating time, duration of hospital stay, blood loss and rate of requiring a vertical incision. Disadvantages of the use of GnRH analogues include the cost, menopausal symptoms during treatment and bone demineralization with prolonged use. While an increased risk of fibroid recurrence has been reported, due to shrinkage of smaller fibroids making them undetectable at surgery, this was not confirmed in a systematic review. While the use of GnRH analogues has been criticized for making the pseudocapsule plane of cleavage between the fibroid and the surrounding myometrium less well defined, this has not been the authors' experience. Intraoperative interventions to reduce blood loss during myomectomy have undergone a Cochrane review by Kongnyuy and Wiysonge (2007). One such method is the use of Bonney's myomectomy clamp (Figure 32.11A), which is placed across the lower uterus to occlude the uterine arteries. It can be used in conjunction with ring forceps to occlude the ovarian blood supply. An alternative is the use of a rubber tourniquet or catheter, placed around the uterus through an incision in the broad ligament at the level of the lower segment. During a long operation, intermittent release of the clamps or tourniquet is recommended every 10–20 min to prevent ischaemic damage to the tissues. Many intraoperative techniques have been advocated to reduce blood loss. Those that have been found to be effective (with weighted mean difference in blood loss with their use given in parentheses) include intramyometrial vasopressin (–299 ml), intramyometrial bupivacaine plus epinephrine (–69 ml), pericervical tourniquet (–1870 ml) and vaginal misoprostol (–149 ml).

The issue of mode of delivery in subsequent pregnancies following myomectomy where the uterine cavity has been breached is controversial. While common advice given to patients is that all myomectomies involving breach of the uterine cavity mandate caesarean sections in subsequent pregnancies, the evidence for this advice is limited (Parker 2007). During pregnancy and labour, rupture of the uterus after fibroid surgery is an extremely rare event. However, rupture after laparoscopic myomectomy may be higher than after abdominal myomectomy.

Hysteroscopic resection

Submucosal fibroids (such as those illustrated in Figure 32.12) are best removed hysteroscopically. Resection of the fibroid via the hysteroscope may be combined with endometrial ablation for the relief of menorrhagia if the woman has completed childbearing. Hysteroscopic surgery has been used for the removal of lesions measuring up to 7 cm in diameter, although many authorities would set a maximum of 3–4 cm (Agdi and Tulandi 2008). With larger fibroids, GnRH analogues can be used to shrink the tumour prior to surgery. Preoperatively, some surgeons use intravaginal misoprostol to soften and dilate the cervix, and allow easier insertion of the instruments. The uterine cavity is distended with a non-conductive glycine solution, and continuous irrigation with an infusion pump is employed to maintain visibility. A loop electrode is placed distal to the myoma, and sliced towards the cervix under vision. At all times, the

EFFECTIVE GYNECOLOGICAL DAY SURGERY, DAVID HEALY & OSWALD PETRUCCO, 1998 LIPPINCOTT—RAVEN PUBLISHERS.

loop should remain under vision to reduce the risk of perforation of the uterus and damage to bowel or other internal organs. Any uterine perforation necessitates abandoning the procedure. Lengthy procedures carry the risk of 'water intoxication' and electrolyte disturbances, and a strict check should be made on the amount of glycine absorbed. The major advantage of hysteroscopic resection is the avoidance of major surgery, as well as easier access to submucosal fibroids compared with the abdominal route.

Some authors (Donnez et al 1990) advocate the use of the neodymium:YAG laser for larger fibroids, after prior shrinkage with a GnRH analogue. Laser ablation can also be used for smaller fibroids.

Laparoscopic myomectomy

Despite laparoscopic myomectomy being performed for almost two decades, there is little evidence and considerable debate about its place in the treatment of uterine fibroids. It is still not clear how the complications of the procedure compare with open myomectomy, and reported results from studies and case series are highly operator dependent. The purported advantages of the technique include shorter hospital stay, less postoperative pain, faster recovery and better visualization of adjacent organs (Agdi and Tulandi 2008). However, there have been reports of a higher risk of recurrence of fibroids, due to the inability to palpate the uterus and remove smaller coexisting fibroids laparoscopically. There is also a possible increased risk of uterine rupture in pregnancy and labour. Larger fibroid uteri may be impossible to remove laparoscopically, although preoperative

Figure 32.12 Submucous fibroids (subtotal hysterectomy specimen).

shrinkage with GnRH analogues may help in these cases. The procedure is challenging, with skills only available at a few centres, and is time consuming compared with an open myomectomy, subjecting the patient to a longer period of anaesthesia.

Generally, the procedure involves intramyometrial injection of epinephrine, followed by enucleation of the fibroid via diathermy incision, laparoscopic suturing in multiple layers of the remaining cavity, and morcellation and removal of the fibroid through one of the laparoscopic ports.

Recurrent fibroids after surgery

Reported cumulative recurrence rates after myomectomy are up to 50% at 5 years, with approximately 20% of women undergoing hysterectomy. It is not clear whether 'recurrent' fibroids after conservative treatment represent regrowth of existing tumours or de-novo development of additional fibroids. The literature is of poor quality with inconsistent reports regarding the definition of 'recurrence', the length of follow-up, the percentage of women lost to follow-up and why, and the use of other treatments which might affect recurrence. From the available literature, a larger preoperative fibroid size, an increased number of fibroid tumours, increasing fibroid penetration into the myometrium and any residual tissue at the completion of the procedure were all associated with increased risk of recurrence. These factors, leading to the development of further symptomatic fibroids after treatment, seem to occur with medical therapies, UAE or myomectomy.

Uterine artery embolization

Transarterial embolization for the successful treatment of obstetric and gynaecological haemorrhage has been practised for 30 years. It has also been used subsequently to treat uterine arteriovenous malformations. The initial report of the use of UAE to treat symptomatic fibroids was by Ravina et al in 1995. Its use has increased in popularity since then, and has been the subject of thorough recent reviews (Hickey and Hammond 2008, Tropeano et al 2008).

Technique

UAE is a percutaneous, image-guided procedure performed by an interventional radiologist. With regional anaesthesia or sedation, an angiographic catheter is placed under X-ray guidance into the uterine arteries via the common femoral artery. Embolic agents (usually polyvinyl alcohol particles or tris-acryl gelatin microspheres) are then injected into both uterine arteries to occlude them. Occlusion is confirmed angiographically and the catheters are removed (Figure 32.13). While the normal myometrium rapidly re-establishes its blood supply due to an extensive collateral circulation, the fibroids are supplied by end-arteries and undergo necrosis. The procedure takes approximately 1 h, and exposes the woman's ovaries to 20 rads, the equivalent of most routine diagnostic imaging procedures. The date of the last menses should be assessed, and a urine pregnancy test should be performed prior to the procedure to exclude pregnancy. Pre-treatment with GnRH agonists may hamper UAE treatment for fibroids and is contraindicated, unlike for surgery.

Clinical outcomes

Treatment efficacy for menorrhagia associated with fibroids is high, with an 85% reduction in heavy menstrual bleeding immediately post procedure, and approximately 80% patient satisfaction at 5 years. While treatment is associated with a 50% reduction in fibroid volume, the reduction in fibroid volume does not appear to correlate with the reduction in symptoms. In comparison with surgical treatment, UAE is associated with a shorter hospital stay (usually 24 h) and faster return to work (7–10 days). It has less risk of major

Figure 32.13 Catheter inserted via right femoral artery. The contrast medium clearly shows marked vasculature around a fibroid prior to embolization.

intraprocedural morbidity, such as bladder and bowel damage. However, long-term patient satisfaction appears to be greater with hysterectomy, with approximately 8–9% of women treated with UAE each year requiring either further UAE or surgery for recurrent symptoms.

Complications

Short-term complications include failure to cannulate either or both uterine arteries (8–11%), local haematoma formation or thrombosis, and femoral artery damage. 'Post-embolization syndrome' occurs in 40% of patients, lasting 3–7 days, and consists of general malaise, mild fever and flu-like symptoms. Severe pain following the procedure is common, requiring hospitalization and narcotic analgesia. Medium-term complications include vaginal expulsion of an infarcted fibroid (10%), which may become obstructed at the cervix. This is more common with submucosal fibroids. The most serious complication in the medium term is intra-uterine sepsis associated with necrosis of the fibroid (1–2%). Two deaths from overwhelming sepsis after UAE have been reported.

Long-term complications include treatment failure (up to 25% of women will require a second procedure within 5 years), permanent ovarian failure and effects on fertility. After UAE, up to 8% of women have permanent ovarian failure, with higher rates for older women. Effects on future fertility and pregnancies are unknown at this time, but could include uterine rupture and intrauterine growth retardation. Although successful pregnancies have been reported following UAE, it should not be recommended at this time for women planning on having children.

MRI-guided focused ultrasound

MRI-guided focused ultrasound uses high-intensity ultrasound waves directed to a precise area of tissue via MRI

(performed concurrently), causing a temperature rise sufficient to induce coagulative necrosis in the tissue (Tropeano et al 2008). The aim is controlled localized thermal ablation of the fibroid tissue, while leaving the surrounding normal tissues undamaged. The ultrasound waves are delivered to the fibroids via the anterior abdominal wall while the patient is sedated and lying prone on the MRI table. The procedure takes approximately 3 h, but patients go home 1 h post procedure and return to work in 48 h.

Preliminary reports suggest that the procedure is associated with less pain and postoperative complications than UAE, but is less effective as the maximum volume of fibroid tissue that can be treated is limited. While there is theoretically less risk of collateral damage to the ovaries, larger scale studies need to be performed before the safety of this new procedure can be compared with UAE.

Future Directions

There continues to be a lack of quality research into the pathophysiology and treatment of uterine fibroids. This is, in part, due to a lack of desire on the part of government bodies to fund research into a condition that does not

cause an increase in mortality. With a lack of quality data from clinical trials, the treatment provided for uterine fibroids continues to be largely driven by individual clinician and patient preference. More comparative trials of alternative treatments for fibroids and related symptoms are required.

Development of non-surgical treatments for uterine fibroids, as well as improvement in understanding of pathogenesis, is hampered by a lack of suitable in-vitro or in-vivo models. Most studies in the literature consist of observational comparisons between fibroid and adjacent normal myometrial tissue. The best available animal model is the Eker rat model, in which 65% of the female *Tsc^{EX/+}* carriers develop fibroids (Walker and Stewart 2005), but their applicability to fibroids in humans is still unclear and they are expensive to maintain. In-vitro models using smooth muscle cells isolated from the fibroids and adjacent myometrium have also been used. However, recent gene expression microarray work has shown that the differences in gene expression patterns of the two cell types diminish over time in culture (Zaitseva et al 2006), including the oestrogen and progesterone receptors that are critical to fibroid growth *in vivo*. This makes work from in-vitro cultures more difficult to translate into clinically relevant data.

KEY POINTS

1. Uterine fibroids occur in 60% of women by 45 years of age, are the most common cause of hysterectomy, and cost the US health system \$US2.1 billion each year in direct surgical costs.
2. The growth of fibroids is sex steroid dependent. They do not occur until the menarche, and regress after the menopause. Progesterone appears to be as important in fibroid growth as oestrogen.
3. Increasing age, Black race, nulliparity, diabetes mellitus, obesity and hypertension have been associated with an increased risk of uterine fibroids.
4. Uterine fibroids are asymptomatic in at least 50% of cases. If asymptomatic, they require no treatment.
5. Sarcoma (leiomyosarcoma) occurs in one in one million women each year, and typically presents as postmenopausal bleeding. Fear of sarcoma is not an indication for surgical treatment of a fibroid.
6. Menorrhagia is the most common symptom attributed to fibroids, occurring in 30–50% of women with fibroids.
7. Adverse reproductive function (reduced implantation and increased miscarriage) is attributable to submucosal fibroids, and possibly intramural fibroids with uterine cavity distortion, but not to subserosal fibroids.
8. Pelvic ultrasound is the best diagnostic test for uterine fibroids at present.
9. Medical management of fibroids may control patient symptoms, but does not result in complete fibroid regression.
10. GnRH analogues may be used to shrink fibroids for 3 months prior to surgery with reduced intraoperative blood loss, reduced length of stay in hospital and less risk of requiring a vertical incision.
11. More comparative data of laparoscopic vs open surgery is required before firm recommendations can be made regarding the relative benefits and disadvantages of each technique.
12. UAE and MRI-guided focused ultrasound are two relatively non-invasive interventional radiological techniques for treating uterine fibroids which show great promise. However, their use is limited by availability and expertise.

Introduction

Endometriosis is one of the most common benign gynaecological conditions. It is second only to uterine fibroids as the most common reason for major surgical procedures in women under 45 years of age. It has been estimated that it is present in between 10% and 25% of women presenting with gynaecological symptoms in the UK and USA (Tyson 1974). These figures are based on the findings of patients who have undergone laparoscopy for diagnostic indications, such as pelvic pain or infertility, or in patients undergoing laparotomy. Although it is such a widespread condition, it is true to say that there is limited understanding regarding its aetiology and pathogenesis, and the condition still arouses much controversy with regard to its diagnosis, treatment and management. Endometriosis varies in severity from minimal disease with a few peritoneal implants to severe disease producing adhesions, deep infiltrating lesions and involvement with ovarian cyst formation.

Definition

Endometriosis is defined as a disease characterized by the presence of tissue that is morphologically and biologically similar to normal endometrium, and contains functional endometrial glands and stroma, in ectopic locations outside the uterine cavity. This ectopic endometrial tissue initially responds to hormones and drugs in a generally similar manner to eutopic endometrium undergoing cyclical changes. Cyclical bleeding from the endometriotic deposit appears to contribute to the induction of a local inflammatory reaction, fibrous adhesion and formation, and, in the

case of deep ovarian implants in the ovary, leads to the formation of an endometrioma or chocolate cyst. Endometrial tissue deep within the myometrium of the uterine wall is termed 'adenomyosis'. This condition is increasingly viewed as a separate pathological entity to that of endometriosis, since it affects a different population of women, probably has a different aetiology and is most often found in the absence of other evidence of pelvic endometriosis.

Prevalence

Continued growth of endometriotic tissue, as with that of the endometrium, is dependent on ovarian steroid hormones, particularly oestrogen. Thus, endometriosis is prevalent in the reproductive years with a peak incidence between 30 and 45 years of age, although it is increasingly being diagnosed in much younger women as the threshold for investigation of gynaecological symptoms utilizing diagnostic laparoscopy has altered. Endometriosis is thus primarily a disease of the reproductive years and is only rarely described in adolescence, when it is associated with obstructing genital tract abnormalities, or in postmenopausal women, where it has been reactivated because of hormone replacement therapy.

No racial differences in the incidence of the disease have been found, except for Japanese women who have been reported to have twice the incidence of Caucasian women (Miyazawa 1976).

The exact prevalence of endometriosis is unknown since precise diagnosis depends on observation of implants, predominantly at the time of laparoscopy or laparotomy. Until simple non-invasive screening tests are developed, the true

prevalence will remain unknown. Current prevalence therefore depends upon identification in women who are either symptomatic or undergoing various operative procedures. The incidence is markedly variable as the data in Table 33.1 show, but the prevalence of endometriosis in the reproductive years is estimated to be approximately 10% (Eskenazi and Warner 1997). Endometriosis commonly affects women during their childbearing years. In the main, this is reflected in deleterious sexual, reproductive and social consequences as a result of its associated painful symptoms and often associated infertility. Symptomatology may extend over several decades of a patient's life because of its often late diagnosis and the recurrent nature of the disease. For individual patients and healthcare systems, it represents a major call upon resource use.

Pathogenesis

The precise aetiology of endometriosis still remains unknown. Indeed, it is often called the 'disease of theories' because of the many mechanisms postulated to explain its pathogenesis. It is likely that no single theory can explain all forms of endometriosis. Different types of endometriosis may have different origins (i.e. they are multifactorial in origin). Peritoneal endometriosis could arise as a result of retrograde menstruation, ovarian endometriosis via coelomic metaplasia, and rectovaginal endometriosis from development within Müllerian duct remnants. The major theories of causation of endometriosis are metaplasia (transformation) of coelomic epithelium, and implantation of endometrial fragments through retrograde menstruation.

Transformation of coelomic epithelium

This theory, first described by Meyer (1919), postulated the possibility of differentiation by metaplasia towards an endometrial-like tissue of the original coelomic membrane following prolonged irritation and oestrogen stimulation. It is proposed that these adult cells undergo dedifferentiation back to their primitive origin and then transform to endometrial cells. If this theory is correct, metaplasia should occur wherever coelomic membranes are present. This theory has many attractions which could explain the occurrence of endometriosis in nearly all the ectopic sites in the presence of aberrant Müllerian cells. What induces this transformation — whether it is hormonal stimuli, inflammatory irritation or other processes — is uncertain. If coelomic metaplasia is similar to metaplasia elsewhere, the frequency of the disorder should increase with advancing age. The clinical pattern of endometriosis is distinctly different from this, with an abrupt halt in the disease with the cessation of menses at the menopause and reduced oestrogen production, thus raising some questions over this theory.

Menstrual regurgitation and implantation (metastatic theory)

As early as 1927, Sampson proposed the metastatic theory, postulating that retrograde menstrual flow transported desquamated endometrial fragments through the fallopian tubes

Table 33.1 Prevalence of endometriosis through various presentations

Presentation	Prevalence (%)
Unexplained infertility	70–80*
Infertile women (all causes)	15–20*
At diagnostic laparoscopy	0–53 [†]
At treatment laparoscopy	0.1–50 [†]
Women undergoing sterilization	2 [‡]
In women with diagnosed first-degree relatives	7 [§]

into the peritoneal cavity (Sampson 1927). Once there, the still viable cells subsequently implanted and began growth and invasion. In support of this theory, experimental endometriosis has been induced in animals with replacement of menstrual fluid or endometrial tissue in the peritoneal cavity. Supporting this theory in humans is the finding that endometriosis is commonly found in young girls with associated abnormalities in the genital tract causing obstruction to the outflow of menstrual fluid (Schiffrin et al 1973). Halme et al (1984) observed bloody fluid at the time of menstruation in the pelvis during laparoscopic assessment, but as this finding occurs in up to 90% of all women, it is regarded as a physiological phenomenon. The high incidence of retrograde menstruation suggests that this phenomenon alone does not give rise to endometriosis, but that some other factor(s) must be involved in development of the disease. These factors could include some alteration in the (uterine) endometrium, altered immune response to retrograde menstruation (hence failure to clear the peritoneal cavity of debris efficiently), or a more favourable peritoneal environment which may stimulate the growth and implantation of ectopic endometrium within the peritoneal cavity itself.

Genetic and immunological factors

Many studies have indicated that there may be a genetic factor related to endometriosis since the disease is more prevalent in certain families. It has been shown that women with an affected first-degree relative have a seven times higher risk of developing endometriosis, which may be severe (Simpson et al 1980, Halme et al 1986). Endometriosis is also more common in monozygotic twin sisters than dizygotic twins, but no association was found with specifically identified tissue types (Simpson et al 1984). Whilst Dmowski et al (1981) demonstrated a decreased cellular immunity to endometriotic tissue in women with endometriosis, no clinically significant immune system abnormality has been observed in women with the disease; hence, the

precise genetic or immune components increasing an individual's potential to develop this disorder are yet to be defined.

Vascular and lymphatic metastasis (Halban's theory)

Halban's theory suggests that distant endometriosis (outwith the abdominal cavity) occurs via vascular or lymphatic spread of viable endometrial cells or fragments. The theory would explain the rare occurrence of endometriosis in lung, limbs and brain, but not in more common sites within the peritoneal cavity and pelvis.

Endometrial disease theory

Many view the superficial implants as 'physiological' lesions which may regress spontaneously. Deep infiltrating lesions and ovarian endometriotic cysts are pathological and arise from cells that have undergone somatic mutations. Such mutations may have been produced by environmental factors (e.g. pollutants, dioxins). These abnormal cells then develop into a 'benign tumour' consisting of endometriotic glands and stroma. For a review on environmental factors in the aetiology of endometriosis, the reader is directed to Missmer and Mohllagee (2008).

Further support of the above theory stems from biochemical differences demonstrated in the endometrium in patients with and without endometriosis (Guidice and Kao 2004). These include differences in the expression of metalloproteinases, tumour susceptibility genes and angiogenic factors. Such changes may allow certain types of retrograde endometrial fragments to implant more readily than others, and this may be due to an underlying inherited genetic tendency.

Iatrogenic dissemination

Transplantation of endometrial cells can occur during gynaecological surgical procedures. This would explain the development of endometriotic nodules in abdominal wall scars following caesarean section, myomectomy and hysterectomy, and in laparoscopic port scars. In addition, implantation at perineal repair can cause endometriosis to develop in episiotomy scars.

Conclusion

The conclusion reached from the above theories is that pelvic endometriosis is probably a consequence of transplantation of viable endometrial cells regurgitated at the time of menstruation from the fallopian tubes into the peritoneal cavity. In addition, transport of endometrial cells may occur by other routes (some iatrogenic). It is unclear whether endometriotic implants are derived from in-situ pluripotent cells generated by metastatic seeding, but it is known that endocrine and immunological factors allow growth and spread within the pelvis and neighbouring organs. Delayed child-bearing, either by choice or infertility, has been implicated as a risk factor for the development of endometriosis. The risk of developing endometriosis also corresponds with cumulative menstruation, menstrual frequency and volume.

Women with shorter menstrual cycles of less than 27 days and longer flows (more than 7 days) are twice as likely to develop the disease compared with women with longer cycles and shorter flows. Thus, many components are necessary to allow endometriotic deposits to implant and subsequently grow (Figure 33.1).

The cell-mediated efferent arm of the immune system controls implantation or rejection of such fragments. In most women, these fragments are not in a favourable state or in a favourable environment for implantation, and are engulfed by macrophages and thus disposed. In women with deficient or altered cell-mediated immunity, implantation of the ectopic fragments allows implantation to occur with subsequent development of endometriotic implants. Such immune changes could be transmitted genetically and could be both qualitative and quantitative, resulting in variable ages of onset, extent and duration of expression. Autoantibody production would be a secondary phenomenon, developing as the number and extent of endometriotic deposits increase.

Peritoneal Fluid Environment in Endometriosis

It has been suggested that peritoneal fluid volume and its contents may be adversely affected by the presence of endometriotic tissue in the pelvis, with possible consequent interference with tubo-ovarian function and/or fertilization and early implantation. Peritoneal fluid is an ultrafiltrate of plasma, and the volumes are very low in normal women. Endometriosis may alter the peritoneal fluid volume by increasing fluid production in the ovary, altering mesothelial permeability or increasing the hydrostatic pressure as a result of altered protein content.

Peritoneal macrophages

Normal peritoneal fluid contains approximately 10^6 cells per ml; 90% are macrophages, and the remainder are lymphocytes and desquamated mesothelial cells. The role of peritoneal macrophages in women with endometriosis has been the source of much interest, and women with endome-

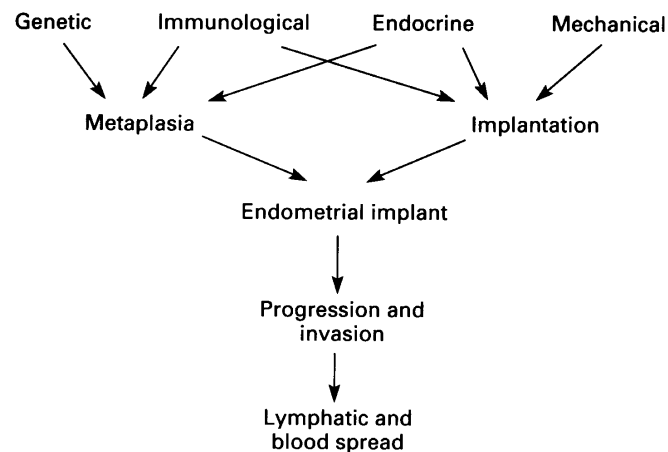

Figure 33.1 Suggested aetiological factors in the pathogenesis of endometriotic implants.

triosis associated with infertility have been reported to have significantly higher concentrations of macrophages in peritoneal fluid than either fertile women or infertile women without endometriosis. Macrophages in patients with endometriosis appeared to be highly phagocytic against spermatozoa *in vitro* compared with those from fertile women or infertile women without endometriosis (Muscato et al 1982). In addition, they are also able to survive better *in vitro* than those from fertile controls (Halme et al 1986). Peritoneal fluid from patients with endometriosis has also been shown to have a cytotoxic effect on in-vivo cleavage of mouse embryos. These findings on the quantitative and qualitative properties of macrophages in peritoneal fluid may partially explain the mechanisms of infertility in patients with endometriosis.

Prostaglandins and prostanoids

The role of prostaglandins and their metabolites in peritoneal fluid in the pathogenesis and symptomatology of endometriosis is controversial. It has been reported that increased levels of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) are found in the peritoneal fluid of patients with the disease (Meldrum et al 1977). In addition, increased peritoneal fluid volume and increased concentrations of the prostaglandin metabolites thromboxane B_2 and 6-keto $PGF_{2\alpha}$ have been noted. Other investigators have found no increase in either the volume of peritoneal fluid or its concentrations of prostaglandins or metabolites (Rock et al 1982). These conflicting reports may reflect the timing of peritoneal fluid sampling and difficulties in assay measurement of the small quantities of substrates, all of which have very short half-lives.

In recent years, it has been appreciated that more subtle forms of endometriosis may be present with only minimal evidence of visual changes in the peritoneum. However, if there are changes in the prostaglandin content of the peritoneal fluid, the mechanisms by which these changes influence endometriosis or its association with infertility remain unclear.

Cytokines and growth factors

A large number of cells, including macrophages, lymphocytes, fibroblasts and epithelial cells, synthesize a wide range of polypeptides of high biological activity within the cytokine/growth factor group. They have multiple effects including the regulation of differentiation, growth and function of a wide variety of cell types. It was generally believed that cytokines were produced in increased amounts as part of the inflammatory process or as part of a response to infection or immune challenge. Cytokines are very potent and active at picogram to nanogram levels, and are difficult to detect and identify. Research activity has been concentrated on the measurement of various cytokines including various interleukins, colony stimulating factors, human necrosis factor and transforming growth factors. To date, no consistent changes between normal, infertile women with and without endometriosis and patients with endometriosis who are not infertile have been reported to satisfactorily explain the aetiology or pathogenesis of the disease.

Peritoneal environment: conclusions

Peritoneal macrophages play an important role in the peritoneal cavity where endometrial tissue fragments often arrive and are likely to adhere to the mesothelial lining. The adherence may be mediated by cell adhesion molecules and other factors produced by activated macrophages. Endometrial tissue will potentially adhere if the regurgitated amount of the tissue is too great, or if the capacity of the intra-abdominal cells to clear the cellular debris is in any way impaired. Once an endometrial fragment has gained adherence, further tissue growth may be promoted by steroids, cytokines, growth factors and angiogenic factors present in peritoneal fluid in a paracrine and autocrine fashion.

Presentation

Endometriosis commonly presents between the ages of 25 and 35 years, although it can present in early adolescence and in postmenopausal women on hormone replacement therapy. The symptoms of endometriosis are variable and often unrelated to the extent of the disease process as currently quantified. The three most common complaints amongst women with endometriosis are dysmenorrhoea, dyspareunia and pelvic pain. The pain symptoms are often cycle related and increase premenstrually. However, it must be stated that the finding of endometriosis may not conclusively link it with painful symptoms in an individual, since the severity of symptoms is rarely correlated with the extent of the disease, and endometriosis is often found coincidentally (during surgery or investigation for other gynaecological conditions, such as infertility) at similar levels in patients not complaining of pain.

Atypical bleeding patterns are a leading symptom in a variety of gynaecological diseases, but may also characterize patients with endometriosis. Premenstrual spotting and menometrorrhagia are frequently noted. On the other hand, cyclical rectal bleeding or haematuria is pathognomonic of the disease and, although rarely observed (1–2% of cases), these symptoms give strong evidence for bowel or bladder involvement. Painful micturition or defaecation at the time of menstruation may be the first signs of progressing disease. The various symptoms of endometriosis as found in various sites of implantation are shown in Table 33.2.

Dysmenorrhoea

Dysmenorrhoea is the most common presenting symptom, affecting 70–80% of women with proven endometriosis. Dysmenorrhoea often occurs with pelvic pain, but patients commonly describe a background of constant dragging, aching pain which may be exacerbated by the menses but is often a different type of pain from the typical cramping nature of spasmodic dysmenorrhoea and often in a different site. Typically, pain starts some days before menstruation as an ache or discomfort, similar to congestive pelvic pain. It worsens and becomes spasmodic with the start of the menses and continues throughout days of bleeding, lessening as menstrual flow ebbs. Unlike 'primary dysmenorrhoea' which starts soon after the establishment of ovulatory cycles, endometriosis-related dysmenorrhoea often starts in the

Table 33.2 Symptoms of endometriosis related to sites of implants

Symptoms	Site
Dysmenorrhoea	Reproductive organs
Lower abdominal pain	
Pelvic pain

Rupture/torsion endometrioma	
Infertility	
Cyclical rectal bleeding	Gastrointestinal tract
Tenesmus	
Diarrhoea/cyclic constipation	
Cyclical haematuria	Urinary tract
Dysuria (cyclical)	
Ureteric obstruction	
Cyclical haemoptysis	Lungs
Cyclical pain and bleeding	Surgical scars/umbilicus
Cyclical pain and swelling	Limbs

early 20s, and is usually very severe, incapacitating and unresponsive to simple/mild analgesics or antiprostaglandins. If endometriosis is untreated, dysmenorrhoea progressively increases in duration, but severity tends to remain constant.

Dyspareunia

Another common symptom of endometriosis is deep dyspareunia resulting from stretching at intercourse of the involved pelvic tissues such as a fixed retroverted uterus, the uterosacral ligaments or rectovaginal septum; or pressure on an involved enlarged, often adherent, ovary. The presence of endometriotic tissue within these areas, however, is not always associated with dyspareunia; perhaps less than half of patients who are coitally active admit to this symptom when deposits are found in these areas. The pain continues for a variable time after intercourse, often as a dull ache. Typically, dyspareunia is exaggerated in the phase before menstruation commences. This pain is more severe in women with deep rectovaginal septum involvement and may result in complete apareunia.

Origin of pain

The basis of the pelvic pain and dysmenorrhoea is uncertain but could reflect stretching of tissues by the menstrual process and an effect of the local production of prostaglandins within the endometriotic implants. The pain also relates to tissue damage and fixity of organs from scar and adhesion formation. What is immediately clear when reviewing patients with endometriosis is the huge variation in extent of symptomatic disease, which does not correlate

with the extent of the observed disease process. In addition, many patients who are asymptomatic are found to have endometriosis, and in some of these patients, severe disease is discovered following laparoscopy during infertility investigations. One possible explanation for this is that in these individuals, the disease may have disrupted the pelvic sensation altogether. Pain may arise from mediator release from the endometriotic deposits (prostaglandins, inflammatory products from macrophages or interleukins) in the early stages of the disease at menstruation. Pain associated with more advanced disease is likely caused by extensive adhesions, ovarian endometriotic cysts or deep infiltration of disease. The pain may result from mechanical compression or disruption of nociceptors, particularly around the uterosacral ligaments.

Non-cyclic chronic pelvic pain

In approximately 30–50% of women with pelvic endometriosis, chronic pelvic pain (CPP) of varying severity, pattern and location is reported. Pelvic pain is arguably the symptom causing the most misery amongst endometriosis sufferers, and is more distressing than infertility. CPP, as with other forms of pain, often produces a serious long-term detrimental effect on the personality, and affects working ability and social and marital life. Possible causes include adhesions, ovarian cysts, peritoneal inflammatory reaction around implants, or involvement of bladder or bowel. Pain may be triggered by ovulation, bowel evacuation or micturition. Pain resulting from adhesions may be provoked or worsened by certain body positions or movements. A common feature of CPP is worsening before and during menstruation.

Menstrual irregularities

In 16% of women, the disease is associated with heavy and/or irregular periods or premenstrual spotting, the causes of which are undetermined.

Other symptoms associated with the menstrual cycle

Direct involvement of the bladder wall can result in haematuria and dysuria occurring at the time of menstruation. Invasion into the muscular coat of the descending colon and rectum (most commonly) can cause cyclical rectal bleeding and painful defaecation (dyschezia), whilst involvement of the small bowel or colon elsewhere may not present until a narrowing of the bowel lumen has occurred with complete or partial obstruction. Rarely, dysmenorrhoea may be associated with symptoms due to extrapelvic endometriosis (e.g. sciatica, groin pain), or cyclical haemoptysis or pneumoperitoneum with lung/pleural involvement. Other rare associations include bleeding, swelling and/or pain in surgical scars, umbilicus or episiotomy site affected by endometriosis.

Correlation of symptoms and severity of endometriosis

The frequencies of the more common symptoms in endometriosis patients are summarized in Table 33.3. Whilst the

Table 33.3 Frequency of the more common symptoms in endometriosis patients

Symptom	Likely frequency (%)
Dysmenorrhoea	60–80
Pelvic pain	30–50
Infertility	30–40
Dyspareunia	25–40
Menstrual irregularities	10–20
Cyclical dysuria/haematuria	1–2
Dyschezia	1–2
Rectal bleeding (cyclic)	<1

symptoms of dysmenorrhoea, dyspareunia and pelvic pain can occur with other gynaecological disorders, it is the combination, cyclical and menstrually related component of several symptoms which should alert the clinician to the potential underlying presence of endometriosis. Many women have delayed diagnosis of their condition, which may mean that it has progressed to a more extensive and potentially less reversible or curable stage at the time of diagnosis.

There appears to be little correlation between sites involved in endometriosis and symptoms. Various 'types' of symptoms can, however, be related to some degree to the system involved (see Table 33.2). However, these do not always correlate with the anatomy and type of pain innervation of the pelvis (for review, see MacLavery and Shaw 1995).

One reason for the apparent lack of correlation between disease severity and symptom severity is that the classification systems for endometriosis thus developed have primarily been directed towards infertility prediction rather than pain symptom severity.

Deeply infiltrating endometriosis is very strongly associated with the presence and severity of pelvic pain. In addition, superficial non-pigmented endometriosis has the capacity to produce more prostaglandin F (PGF) than pigmented classic powder burn lesions. PGF is implicated in pain causation (Vernon et al 1986). Thus, in the early, less florid stages before it has become destructive and more easily recognized, endometriosis may be producing large quantities of PGF and hence possesses greater potential to increase the severity of pain. The type of pain may alter with disease progression, with constant pain and exacerbation at the menses initially in the disease, and pain later becoming continuous due to scar formation and organ fixity.

Endometriosis and Infertility

It is accepted that endometriosis resulting in structural damage to the tubes and ovaries causes infertility. However, what is less clear is whether the milder forms of endometriosis are also the cause of infertility in otherwise asymptomatic patients.

Table 33.4 Possible mechanisms of causation of infertility with mild endometriosis

Problem area	Mechanism
Ovarian function	Endocrinopathies <ul style="list-style-type: none"> • Anovulation • Luteinized unruptured follicle syndrome • Altered prolactin release • Altered gonadotrophin midcycle surge
	Luteolysis caused by prostaglandin $F_{2\alpha}$
	Oocyte maturation defects
Coital function	Dyspareunia causing reduced penetration and coital frequency
Tubal function	Alterations in tubal and ciliary motility by prostaglandins
	Impaired fimbrial oocyte pick-up
Sperm function	Phagocytosis by macrophages
	Inactivation by antibodies
Endometrium	Interference by endometrial antibodies
	Luteal-phase deficiency
Early pregnancy failure	Increased early abortion
	Prostaglandin induced or immune reaction

Endometriosis was one of the most frequently made diagnoses in couples undergoing infertility investigation, when routine use of laparoscopy for investigation of such couples was employed, in past years. The assumption was made that endometriotic implants are responsible for the patient's inability to conceive. Estimates of the incidence of endometriosis in the general population of reproductive age vary between 2% and 10%. From retrospective studies in infertile patients, the incidence has been reported as being between 20% and 40% (Mahmood and Templeton 1990). This increased incidence in infertile patients has led many clinicians to consider the endometriotic implants to be responsible, in some way, for the associated infertility. The question is how, and a number of suggested mechanisms have been reported. These are summarized in Table 33.4. For the majority of these potential causes, there are few or no consistent data to provide a sustainable explanation. Thus, the nature of the relationship between mild endometriosis and infertility remains unresolved.

Although there may be some debate about the role of filmy peritubal or periovarian adhesions in infertility, it is accepted that with increasing severity of endometriosis, adhesions become more common and the chances of a natural conception decrease. The majority of specialists would divide such adhesions if found at laparoscopy and if appropriate consent had been obtained, although laparoscopy is no longer routinely undertaken in asymptomatic infertile women. Evidence that the treatment of endometriosis benefits fertility would provide proof that endometriosis is linked with infertility. Historically, many studies have utilized ovarian-suppression treatments with progestogens, danazol and/or gonadotrophin-releasing hormone (GnRH)

analogues in the hope of treating endometriosis and enhancing fertility. The majority of these patients had minimal or mild endometriosis (see later for classification). These studies show that 3–6 months of medication prevents fertility during treatment, but does not increase pregnancy rates following treatment cessation. Meta-analysis showed no difference in pregnancy rate between ovarian suppression and no treatment (relative risk 0.98; confidence interval 0.81–1.15) (Hughes et al 1993, Adamson and Pasta 1994). There was no difference among different ovarian-suppression agents, and the current recommendation is that ovarian suppression in the infertile patient is not justified because of lack of effectiveness on improving conception rates over a conservative approach alone.

Laparoscopic surgical destruction, excision or laser ablation of endometriotic deposits has become popular in recent years and is helpful in pain management of selective endometriosis patients (see later). However, its role in patients with endometriosis and infertility without tubo-ovarian adhesion, endometriomas or other pathology is in question. The ENDOCAN randomized trial from Canada showed a higher pregnancy rate at 9 months in patients who had undergone surgical destruction of endometriotic deposits (and any adhesions present) compared with the control (no treatment) arm (37.5% vs 22.5%). The number needed to treat to create a pregnancy was 7.7 (Marcoux et al 1997). However, a smaller, prospective randomized controlled trial from Italy did not show any difference in pregnancy rates between the treatment and control groups (19.6% vs 22.2%) (Parazzinni 1999). There is a need for more large randomized controlled trials to investigate the role of surgery in such patients.

Conclusions

To date, it is not known how mild endometriosis (without tubo-ovarian disease or adhesions) causes infertility, but it is recognized that such patients have a reduced fecundity rate. Until the underlying cause (if any) is found and appropriate corrective therapies are available, such asymptomatic patients are best treated along the lines of unexplained infertile couples (see Chapters 20 and 22) with treatment options based on age and duration of infertility.

Diagnosis

The diagnosis of endometriosis still presents several problems resulting from the similarities in clinical symptoms produced by endometriosis to other benign gynaecological disorders, and to several non-gynaecological disorders, particularly related to the gastrointestinal system.

Symptomatic pointers

No single symptom is pathognomic of endometriosis, but severe dysmenorrhoea (pain sufficient to require time off work and/or to interfere with normal everyday activity) is highly predictive. Dyspareunia and pelvic pain are less predictive in the absence of severe dysmenorrhoea (Overton and Kennedy 1993). These gynaecological symptoms may, however, be of diagnostic help in the suspicion of endome-

triosis, which should be a differential diagnosis in any patient presenting with worsening dysmenorrhoea, pelvic pain and/or dyspareunia or with other cycle-associated symptoms relating specifically to the bowel, bladder or localized skin lesions (see Table 33.2 and Box 33.1). In endometriosis, the associated dysmenorrhoea extends to the pre- and postmenstrual phase, and is typically of secondary onset and progressive rather than being present from the onset of the menarche. In women presenting with pelvic pain, a history of whether or not this relates to the menstrual cycle is helpful in differentiating other aetiological causes of pain. In those with associated marked bowel symptoms, a trial of treatment for irritable bowel syndrome may be worthwhile before considering referral for diagnostic laparoscopy, although other pathologies may be present concurrently (see Box 33.2).

Clinical examination

Clinical abdominal examination may demonstrate local tender nodular lesions in a caesarean section or laparotomy scar, or at the umbilicus or other site of a laparoscopy port. Gynaecological speculum examination may visualize endometriotic lesions as clear red or bluish cysts or nodules in the vagina, most commonly in the posterior fornix, or on the cervix. This visual diagnosis cannot substitute for histological confirmation even if bleeding occurs from the lesions at the time of menstruation.

Box 33.1 Symptoms suggestive of the presence of endometriosis

Primary symptoms

- Dysmenorrhoea: secondary onset
- Pain not normally controlled by simple analgesics or oral contraceptive pill
- Pain severe enough to cause significant incapacitation

Plus two or more in addition

- Dyspareunia: deep
- Pelvic pain: worse in premenstrual phase
- Dysmenorrhoea/pain continues with postmenstrual days

Less common associated symptoms

- Infertility
- Bleeding from rectum coinciding with menstruation
- Pain at micturition or defaecation: worse or only at time of menses

Box 33.2 Differential diagnosis of endometriosis

- Pelvic infection: chronic pelvic inflammatory disease
- Adhesions: postoperative or following pelvic inflammation
- Ovarian cyst: torsion or haemorrhage into a cyst
- Haemoperitoneum: ruptured corpus luteum or ectopic
- Large bowel: irritable bowel syndrome, diverticulitis, ulcerative colitis, obstruction
- Small bowel: Crohn's disease, obstruction
- Musculoskeletal

Pelvic examination often reveals induration of the uterosacral ligaments or nodules in the pouch of Douglas or rectovaginal septum. Involvement of the ovaries can lead to the development of endometriotic cysts which eventually become large enough to be palpable. There may be fixation of the uterus in retroversion, with the immobilization of the ovaries by adhesion formation, and tenderness, particularly when the patient is examined in the immediate premenstrual phase of the cycle. These clinical findings, whilst not specific to endometriosis, may add to the suspicion of the presence of the disease from the pointers obtained in the history.

Pelvic endometriosis

Pelvic endometriosis has been defined as endometriotic implants involving the peritoneum, anterior and posterior cul-de-sac and pelvic side walls, and the surfaces of the uterus, tubes and ovaries.

Diagnosis of pelvic endometriosis cannot be made with absolute certainty from symptoms or examination alone, and laparoscopic examination may be required to confirm the initial clinical diagnosis. The role of laparoscopy is to:

- provide direct visualization of the endometriotic lesions;
- present an opportunity to biopsy suspected areas, if desired;
- stage the disease by extent, type and site of lesions;
- evaluate the extent and type of adhesions present; and
- provide an opportunity for concomitant laparoscopic surgical treatment, if felt appropriate.

The laparoscopic features of pelvic endometriosis are many and varied, and it is clear that a carefully undertaken laparoscopy by an experienced surgeon is essential if cases are not to be missed at this diagnostic opportunity. Whenever there is any doubt, the need for biopsy confirmation is paramount. Careful recording of the laparoscopic findings is essential and photographic records are most helpful if patients are to be referred on for further management.

Morphology of the typical black lesions

The typical peritoneal endometriotic lesion is described as a 'powder burn' which results from tissue bleeding and retention of blood pigments, producing a brown-black discoloration of the tissue. In the early stages, these lesions may appear more pink, red and haemorrhagic, and develop into brown-black lesions with increasing time. Eventually, discoloration disappears altogether and a white plaque of old collagen is all that remains of the endometriotic implant (Figure 33.2).

Scarring in the peritoneum surrounding implants is also a typical finding. Apart from encapsulating an isolated implant, the scar tissue may deform the surrounding peritoneum, resulting in development of adhesions between adjacent pelvic structures. These adhesions are commonly found between the mobile pelvic structures, particularly the posterior leaf of the broad ligament and the ovary, and the dependent sigmoid colon and posterior aspect of the vagina and/or cervix.

Figure 33.3 Active endometriosis on the uterosacral ligament.

Source: Overton C, Davis C, McMillan L, Shaw RW 2007 *An Atlas of Endometriosis*, 3rd edn. Informa Healthcare, London.

Classification and morphology of subtle appearances

More recently, more subtle laparoscopic appearances have been reported which were confirmed on biopsy as being due to endometriosis (Donnez and Nisolle 1991). The subtle forms are more common and may be more active and more important than the puckered black lesions that represent the later stages of the disease. These other peritoneal lesions include red lesions and white lesions.

Red lesions

- Red flame-like lesions on the peritoneum, with the appearance of red vascular excrescences in the broad ligament and uterosacral ligaments, largely due to the presence of active endometriosis surrounded by stroma (Figure 33.3).

- Glandular excrescences which closely resemble the mucosa of the endometrium as seen at hysteroscopy; biopsy reveals the presence of numerous glandular elements (Figures 33.4 and 33.5).

White lesions

- White opacification of the peritoneum. These lesions contain an occasional retroperitoneal glandular structure, scanty stroma surrounded by fibrotic tissue and connective tissue (Figure 33.6).
- Yellow-brown peritoneal patches called 'café-au-lait spots', found in the cul-de-sac, broad ligament or over the bladder. Histologically, they are similar to findings of white opacification; the yellow-brown patches indicate the presence of haemosiderin.
- Circular peritoneal defects of the pelvic peritoneum, uterosacral ligaments or broad ligament. Serial section has demonstrated the presence of endometrial glands in approximately 50% of these structures (Figure 33.7).

Figure 33.4 Active endometriosis with glandular or stromal components in a biopsy specimen from a red lesion.

Figure 33.5 Vesicular implant of the ovarian fossa.
Source: Overton C, Davis C, McMillan L, Shaw RW 2007 *An Atlas of Endometriosis*, 3rd edn. Informa Healthcare, London.

Ovarian endometriosis

The ovary represents a unique site for implantation of endometrial fragments, as levels of gonadal steroids are several times higher than those in the general circulation or peritoneal cavity.

Superficial endometriosis

Superficial implants on the ovary resemble implants in other peritoneal sites. Comparable features are typical black, red or white lesions (Figure 33.8).

Subovarian adhesions

Subovarian adhesions may be confined to the peritoneum of the ovarian fossa, and are distinct from adhesions characteristic of previous salpingitis or peritonitis; this connective tissue often contains sparse endometrial glands.

Figure 33.7 Peritoneal pouches near right uterosacral ligament associated with endometriosis.

Endometrioma

The pathogenesis of the typical ovarian endometriotic cyst or endometrioma has now been clarified. It is a process originating from a free superficial implant which is in contact with the ovarian surface and is sealed off by adhesions (Figure 33.9). A pseudocyst is thus formed by accumulation of menstrual debris from shedding and bleeding of the small implant, resulting in fluid collection. Progressive invagination of the ovarian cortex occurs and the associated inflammatory reactive tissue progressively thickens the inverted cortex. Outgrowths through the endometrial epithelium, with or without stroma, extend over the surface or become embedded in the fibroreactive tissue covering the wall. This pathogenesis explains the typical features of an endometrioma such as frequent location of the cyst, adhesions on the anterior side of the ovary opposing the posterior side of the parametrium or, when on the posterior aspect of the ovary, adhesions to the ovarian fossa. The contents of the cyst are, to a large extent, fluid which represents the debris from cyclical menstruation (Figures 33.10 and 33.11).

Figure 33.8 Superficial lesions on posterior aspect of ovary.

Figure 33.9 Diagrammatic representation of endometriosis formation, beginning on serosal surface and invaginating into cortex.

There is usually a well-defined separation between the normal adjacent ovarian stroma and the cyst wall, but whilst the epithelial lining of the cyst may initially resemble the endometrium, with increasing time and size, pressure atrophy compresses the epithelium to a flat cuboidal pattern.

Ovarian endometriomas rarely occur in the adolescent, but incidence increases with age. Laparoscopic features of a typical endometrioma include ovarian cysts not greater than 12 cm in diameter, adhesions to the pelvic side wall and/or the posterior broad ligament, powder burns, minute red or blue spots with adjacent puckering on the surface, and the presence of the characteristic tarry, thick, chocolate-coloured fluid content (see Figure 33.10).

Extrapelvic endometriosis

Extrapelvic endometriosis is defined as endometriotic-like implants elsewhere in the peritoneal cavity or other body cavities. Extrapelvic endometriosis has been reported in virtually every organ, system and tissue, but far less frequently than pelvic endometriosis. Overall, the incidence of extrapelvic disease represents less than 12% of reported cases of endometriosis, and it appears that the frequency of occurrence decreases with the distance from the pelvis.

Urinary tract endometriosis

Endometriotic implants can be found over the pelvic ureter and bladder, with unilateral involvement of the ureter and potential obstruction to drainage of the kidney more common than bilateral involvement. The highest incidence of involvement of endometriosis of the urinary tract involves the bladder, followed by the lower ureter and the upper ureter, with the kidney itself being the least common site.

Common symptoms associated with bladder endometriosis are cyclical haematuria, dysuria, urgency and frequency. Ureteral endometriosis eventually induces partial or complete obstruction of the ureter which will always require surgical management; either segmental resection

Figure 33.10 Left ovarian endometrioma.

Figure 33.11 Enlarged left ovary containing a deep-seated endometrioma (left) and another ovary with superficial deposits on the ovarian capsule, in addition to others on the peritoneal surface in the pouch of Douglas (right).

and reanastomosis, or reimplantation of the ureter. For temporary resolution of hydronephrosis, the insertion of a ureteric stent may be necessary until definitive surgery is undertaken.

Gastrointestinal tract endometriosis

Extrapelvic endometriosis is most commonly found with involvement of the gastrointestinal tract. The most common site for involvement is the sigmoid colon, followed by the rectum, the ileocaecal area and the appendix. The transverse colon and small bowel are infrequently involved.

When there is involvement of the gastrointestinal tract, endometriosis is not the first diagnosis in the majority of patients. Symptoms are non-specific and include abdominal pain, distension, disturbed bowel function and rectal bleeding. The occurrence of cyclical rectal bleeding at the time of menstruation is the key pointer to endometriosis. Discomfort and pain at defaecation (dyschezia) is a hallmark of involvement of the rectosigmoid area. Besides rectal bleeding, there is often little to observe in the mucosal lining at endoscopy since involvement is deep within the smooth muscle wall. In advanced stages, a typical irregular stricture formation can be demonstrated on barium enema, and the use of magnetic resonance imaging (MRI) demonstrates the extent of involvement in the rectovaginal septum. Superficial implants on the serosal surface of the bowel are not uncommon and can be treated by laser destruction or medical suppressive therapy. However, involvement of the smooth muscle of the bowel wall and evidence of stricture formation will require surgical excision by open or laparoscopic approaches, depending upon the localized site of involvement.

Involvement in surgical scars

Endometriosis in surgical scars has been reported in the umbilicus or other port sites following laparoscopy, in abdominal incisions following gynaecological surgery and caesarean section, and in the perineum within episiotomy scars following childbirth (Figure 33.12). Such patients

Figure 33.12 Endometriosis in episiotomy scar. The patient presented with cyclic, tender swelling in the perineum.

present with a painful, palpable swelling, usually more symptomatic at the time of menstruation. Occasionally, some women report discharge or cyclical bleeding occurring perimenstrually from the lesions. While medical treatment will control the symptoms with effective suppression of menstruation, surgical excision of the nodule will normally be necessary in the long term.

Vaginal endometriosis

Endometriosis of the vagina may occur following hysterectomy, most commonly in patients with a past history of endometriosis and in whom an ovary has been conserved. It has also been reported in women who have undergone bilateral oophorectomy, but who have been commenced on hormone replacement therapy soon after surgery.

However, endometriosis involving the posterior vaginal fornix is found in most instances as a continuance of deep infiltrating disease from the cul-de-sac and rectovaginal septum. Bimanual examination of these patients is essential as the small vaginal lesions do not represent the full extent of involvement, and assessment at or near the time of menstruation may be the most informative.

Pulmonary and thoracic endometriosis

Cyclical haemoptysis and cyclical haemo-/pneumothorax have been reported in patients in whom endometriosis has been found involving the lungs and thorax. Pulmonary thoracic endometriosis is uncommon. Hormone therapy is of value as an interim measure, but as with other deep-seated extrapelvic endometriosis, recurrence is inevitable on cessation of medical treatment, and surgical excision would be the eventual treatment of choice.

Non-invasive methods of diagnosis

It is an unsatisfactory situation that in order to diagnose endometriosis with certainty, an invasive, albeit minor, surgical procedure in the form of laparoscopy needs to be performed. This can readily be justified for making the initial diagnosis, but if the nature of the disease is of recurrence for the majority of patients throughout their reproductive life, this may involve repeat laparoscopies on many occasions if one is to be certain that the disease process has returned. Attempts have therefore been made to provide a non-invasive test which is highly sensitive and specific for endometriosis. Currently, such a test eludes investigators, although a number of adjunctive non-invasive tests may be contributory in the management of patients.

Serum markers: CA125

The most widely used serum marker for endometriosis has been the monoclonal antibody OC125, raised against a human ovarian cancer cell line containing the antigen designated 'CA125'. CA125 is a high-molecular-weight glycoprotein found in over 80% of cases of epithelial ovarian carcinoma. Investigation leads to the conclusion that CA125 is possessed by many tissues present in the pelvis, as well as more distant sites including the pericardium and the pleura. Moderate elevation of serum CA125 has been observed in endometriosis, particularly in patients with severe disease (Barbieri et al 1986, Pittaway and Douglas 1989). In these studies, serum levels in excess of 35 u/ml were used as a cut-off point, but sensitivity and specificity have proved inadequate for the use of CA125 as a screening test for endometriosis. However, in individuals in whom the disease has been confirmed and treated, an increase in serum levels above 35 u/ml may be a useful marker of disease recurrence.

Monocyte chemotactic protein-1

Monocyte chemotactic protein-1 (MCP-1) is a member of the small inducible gene family which plays a role in the recruitment of monocytes to sites of injury and inflammation. Levels of MCP-1 have been shown to be increased in the peritoneal fluid of women with endometriosis (Arici

et al 1997) and in the serum of such patients compared with controls (Pizzo et al 2002), particularly in patients with early disease. Further investigation needs to be undertaken to evaluate the potential value of measuring MCP-1 in the non-invasive diagnosis of endometriosis.

Other potential markers

Since endometriosis is an inflammatory process, a number of possible inflammation markers are being investigated (e.g. RANTES, interleukins), and proteomic analysis may subsequently provide a serum non-invasive marker. However, to date, these remain research tools and have lacked enough specificity to be adopted clinically.

Imaging techniques

Ultrasound

Ultrasound examination of the pelvis may be useful in delineating the presence and aetiology of ovarian cystic structures. The characteristic pictures on ultrasound are different when there is a large proportion of blood, such as haemorrhagic corpus luteum cysts or endometriomas, which in a minority of cases may be echo free. However, the walls of an endometrioma are irregular as opposed to the smooth wall of the simple ovarian cyst. The most common pattern is for the chocolate cyst to contain low-level echoes or lumps of dense high-level echoes representing blood clots. The picture may sometimes be confused if there are several cysts in different phases of evolution (see Figure 33.13).

Transrectal ultrasound may be of value before surgery in patients in whom rectal/rectovaginal septum involvement is suspected. This method permits measurement of the distance between the lesion and anal verge, as well as assessment of extrinsic compression and lesions in the rectal submucosal layer (Abrão et al 2004). This method is limited to evaluating the rectosigmoid and retrocervical region. It is

Figure 33.13 Transvaginal ultrasound scan showing the typical ground-glass appearance of endometrioma.

Source: Overton C, Davis C, McMillan L, Shaw RW 2007 *An Atlas of Endometriosis*, 3rd edn. Informa Healthcare, London.

advisable to undertake such examinations 1 h after a simple rectal enema.

Ultrasound may also be useful to identify hypoechogenic nodules in the bladder wall when bladder involvement is suspected, most often in the vesico-uterine fold.

Computed tomography scans and magnetic resonance imaging

Computed tomography (CT) provides better definition than ultrasound in many situations, but it has not established a role in the assessment of pelvic endometriosis. MRI, which is more expensive and has currently been used in a limited number of patients with ovarian endometriomas, has not proved to be diagnostic since, again, there has been a significant overlap between the MRI scanning appearances of endometriomas and cystic adenomas.

Ultrasound, CT and MRI scanning do not appear to be of any help in the diagnosis of peritoneal endometriosis, the deposits of which are too small to be detected by current technology, although various strategies utilizing enhancement agents are being investigated. However, MRI of the pelvis is an additional tool for the diagnosis of pelvic deep infiltrating endometriosis (Bazot and Darai 2005). MRI is unable to precisely define the intestinal layer affected by the lesion, and rectosigmoidoscopy or colonoscopy may be necessary. Even when cyclical rectal bleeding occurs at menstruation, no overt mucosal lesion may be visualized in such patients since the lesions are submucosal. However, external compression or stricture formation may be seen and may also be demonstrated by barium enema studies.

Cystoscopy

The bladder lesions of endometriosis are extrinsic, invading the muscular layer and then finally the mucosa. Hence in the earlier stages of development, cystoscopy may show no mucosal lesions, but is useful to exclude other causes of haematuria and dysuria (interstitial cystitis, vesicular neoplasias) and in the follow-up of excised/treated lesions involving the bladder.

Classification Systems

Over the last three decades, various classification systems have been proposed which attempt to standardize criteria on which the severity of endometriosis could be based. Such a system, if available, would help in the critical assessment of performance of various forms of treatment, and hopefully provide meaningful prognostic indicators. No classification system so far devised has received uniform acceptance; all have suffered from various pitfalls which make it difficult to compare treatment results. The most recent attempt to provide a standardized classification for uniform use has been the Revised American Society for Reproductive Medicine Classification of Endometriosis (American Society for Reproductive Medicine 1996), shown in Figure 20.4. This serves to record the sites of deposits accurately and makes some effort to differentiate between superficial and deep-seated disease, as well as the presence or absence of adhesions. Whilst it offers a differential weighting to the score given to different types of endometriosis,

it must be appreciated that these scores are arbitrary. Classification of the extent of the disease as minimal, mild, moderate or severe is certainly helpful in explaining the problem to the patient, and perhaps in determining whether a medical, surgical or combined medical and surgical approach is the most logical treatment step, at least in relation to fertility outcome.

In addition to the Revised American Fertility score, it may be helpful to chart the exact sites of all implants and their sizes; a method used in the scheme of Additive Diameter of Implants (ADI score) described by Doberl et al (1984), gives a simple quantitative valuation of alteration of the volume of endometriotic disease, although not the activity. For each square millimetre of disease, a score of 1 is given. The ADI score helps to quantify the volume of disease and may be useful in evaluating the response to treatment options.

The major pitfall of any scoring system has been the lack of correlation between the score, or severity of the disease, and the degree of symptoms experienced. What is most important for patient management is an accurate record of the extent and site of each deposit.

These days, most laparoscopic camera systems have the facility to record pictures, and representative pictures before and following treatment are useful records to record the stage of disease and for referral on to other colleagues.

With increasing understanding of the morphological changes of deposits and their relationship to ovarian steroid hormones, and the precise colour and type of each lesion, more accurate selection of treatment options may become possible. Accurate records are vitally important to prevent needless repeat laparoscopies for patients referred to secondary and tertiary referral centres when laparoscopies have been performed previously.

Treatment: General Principles

Endometriosis is a particularly difficult disease to treat. Often, response to therapy relies on recognition of the disease in its earliest possible stages. With most treatment modalities, there is eventual recurrence in up to 60% of cases. Thus, there is no known permanent cure and eventually clinicians have to proceed to surgical oophorectomy in selected cases; this offers the most effective available treatment to date. In addition, in minimal and mild disease (according to the Revised American Fertility Society Classification), particularly in asymptomatic cases presenting with infertility alone, controversy exists as to whether treatment should be given, since no control studies have shown a significant increase in fertility rates following such ovarian-suppression therapies. However, placebo-controlled studies in such cases have shown that endometriosis tends to be a progressive disease for many patients (Thomas and Cooke 1987), and hence treatment may at least arrest progression or eradicate disease for significant intervals.

When endometriosis is associated with symptoms, particularly pain, there can be no doubt that treatment is of benefit, at least in relieving those symptoms for a period of time.

The treatment should be individualized, taking into account the patient's age, wish for fertility, severity of symp-

toms and extent of disease (see Box 33.3). An important aspect of therapy is a sympathetic approach, with adequate counselling and explanation to the patient that will also ensure her compliance whilst on therapy.

Medical Treatments

Ectopic endometrial tissue responds to endogenous and exogenous ovarian steroid hormones in a fashion similar to that of normal endometrium. Thus, a hormonal approach which suppresses oestrogen–progesterone levels and which prevents cyclical changes and menstruation should be beneficial in its treatment. In the hypo-oestrogenic state following the menopause, atrophy of the normal endometrium and atrophy and regression of endometriotic deposits occur. Administration of progestogens opposes the effect of oestrogen on endometrial tissue by inhibiting the replenishment of cytosolic oestrogen receptors. Progestogens also induce secretory activity in endometrial glands and decidual reaction in the endometrial stroma.

The success of various hormonal therapies depends to a large extent on the localization and type of the endometriotic lesions. Superficial peritoneal and ovarian serosal implants may respond better to hormone therapy than deep ovarian or peritoneal lesions or lesions within organs (e.g. bladder and rectum), where symptoms rapidly recur after medical therapy and most require ultimate surgical excision.

Box 33.3 Planning endometriosis treatment: factors to consider

- Patient's age
- Wish for future conception
- Contraception need
- Severity of pain and impact on life style
- Type, extent and location of deposits
- Involvement bowel, bladder or renal tract
- Availability of resources
- Surgical expertise of gynaecologist
- Patient's preference

The treatment of endometriosis has undergone a remarkable evolution in the last 40 years. In the past, testosterone, diethylstilboestrol and high-dose combination oestrogen–progesterone pill preparations were used with some success. However, therapies which induce decidualization (pseudopregnancy regimes) or suppress ovarian function (pseudomenopausal regimes) appear to offer the best chance of inducing clinical remission of endometriosis (Table 33.5).

Analgesics

Simple analgesics (e.g. paracetamol, aspirin) can be used but have often been tried and failed prior to referral to a specialist gynaecologist. They are helpful to a degree for the mild-to-moderate pain of endometriosis. A clinical feature in many women with the disease, as it progresses, is the failure of simple analgesics to work, and more potent agents (Tramadol, Diclofenac etc.) may be required.

Prostaglandin synthetase inhibitors

An association with prostaglandin release and dysmenorrhoea has long been established. One might therefore expect that prostaglandin synthetase inhibitors (PGSIs) might have a beneficial effect in treating the symptoms of endometriosis. PGSIs are a heterogeneous group of non-steroidal inflammatory agents which act mainly by inhibiting the production of prostaglandins, although some (fenamates) also antagonize prostaglandins at the target level. These agents are perhaps beneficial in the early stages of initial or recurrent disease, but when symptoms become more severe, they are usually inadequate by themselves to control symptomatology.

There are surprisingly few data on the evaluation of the effectiveness of analgesics or PGSIs in treating endometriosis-associated pain.

Gestagen and antigestagen treatment

A state of pseudopregnancy can be induced effectively by the continuous administration of progestogenic preparations. The progestogens used are derivatives of progesterone (dydrogesterone or medroxyprogesterone acetate) or

Table 33.5 Various hormonal states and their effects upon normal endometrium and ectopic endometrial deposits

Hormonal state	Effects on endometrium	Effects on endometriotic implants
Oestrogenic e.g. exogenous oestrogens	Proliferative activity and hyperplasia	Proliferative activity and hyperplasia
Hypo-oestrogenic e.g. postmenopause, pseudomenopause regimens, post-ophorectomy, GnRH analogues, aromatase inhibitors	Atrophic changes	Atrophy, regression and resorption
Progestational e.g. pregnancy, exogenous progestogens, pseudopregnancy treatment, LNG-IUS	Secretory activity and decidualization	Secretory activity, necrobiosis and resorption
Androgenic e.g. danazol and its metabolites, gestrinone	Atrophy	Atrophy and regression

GnRH, gonadotrophin-releasing hormone; LNG-IUS, levonorgestrel intrauterine system.

19-nor-testosterone (norethisterone, norethisterone acetate, norgestrel, ethynodrel and lynoestrenol).

The use of progestogens induces a hyperprogestogenic/hypo-oestrogenic state. Treatments are available orally or injected as a depot formulation, and are administered for 6–9 months. The results achieved appear to be comparable to those achieved with combined oral oestrogen–progestogen preparations in the past. The side-effects most commonly seen with progestogen usage include breakthrough bleeding, weight gain, abdominal bloating, oedema, acne and mood changes.

The adverse effects of some progestogens on circulating levels of low- and high-density lipoproteins may determine the choice of progestogen if long-term administration is planned.

The oral progestogens used most commonly to attempt to induce amenorrhoea are:

- medroxyprogesterone acetate (30–40 mg/day);
- dydrogesterone (20–30 mg/day); and
- norethisterone (10–25 mg/day).

Long-acting depot preparations of progestogens (Depo-Provera 150 mg, 3 monthly) can be used. However, the author's personal experience has been that in order to avoid the initial problems (e.g. erratic/irregular vaginal bleeding), this may be best commenced once amenorrhoea has been achieved with other agents (e.g. GnRH analogues) for a few months. Depo-Provera has been shown to be as effective as the combined oral contraceptive pill (COCP) or danazol in reducing endometriosis-associated pain (Vercellini et al 1996).

Levonorgestrel intrauterine system

The levonorgestrel intrauterine system (LNG-IUS) was introduced as a long-acting contraceptive coil method, but its utility as a treatment option in gynaecology has been expanded into the treatment of menorrhagia due to dysfunction (unexplained) causes (see Chapter 31) and more recently in the treatment of endometriosis.

The steady low level of LNG achieved in the peripheral circulation appears to have a direct effect on the growth of endometriotic deposits through peritoneal fluid. The suppression of menstruation, or marked reduction of flow, may also be beneficial in reducing the amount of retrograde men-

strual regurgitation, which may help to prevent new disease induction.

Effectiveness data come from two randomized controlled trials. In a study comparing LNG-IUS with expectant management, significantly lower pain scores were achieved in the LNG-IUS women at 12 months (Vercellini et al 2003). In the second trial, LNG-IUS was compared with GnRH analogue; after 6 months of treatment, both treatments were equally effective in reducing pain scores (Petta et al 2005).

Larger trials are required, along with long-term data, to enable clinicians to determine the types of disease and subjects with endometriosis in which the LNG-IUS may be of benefit.

Combined oral contraceptive pill

The COCP reduces pain associated with endometriosis, is well tolerated and can be continued long term for the control of symptoms in healthy women without risk factors. One of a number of 'high-dose' COCPs may be administered, and regimes often utilize COCPs prescribed continuously for three cycles to reduce the frequency of menstruation. If breakthrough bleeding occurs before planned interval bleeding, changing to another preparation with a higher progestogenic content is advocated.

Side-effects such as weight gain, headaches, breast enlargement and/or tenderness, nausea and depression may occur. The risk of thromboembolism is increased, and a personal previous history or family history of venous thromboembolism may involve screening for risk factors, including factor V Leiden polymorphism, prior to administration.

Gonadotrophin-releasing hormone agonists

Surgical castration is known to be an effective therapy for severe endometriosis. Thus, the possibility of inducing a reversible medical castration with the continued administration of GnRH agonists has been investigated as an alternative therapy in endometriosis. Modification of the native GnRH molecule with substitution, particularly in positions 6 and 10, with alternative amino acids produces agonistic analogues with a reduced susceptibility to degradation and hence a prolonged therapeutic half-life (Figure 33.14). Continued administration of these analogues induces pituitary gonadotrophin desensitization via downregulation of GnRH

receptors and an eventual state of hypogonadotrophic hypogonadism. Reduced gonadotrophic stimulation of the ovaries leads to cessation of follicular growth and reduction in ovarian steroidogenesis, with circulating 17β -oestradiol levels falling to those observed in the postmenopausal range (typically less than 100 pmol/l).

A large amount of data has now appeared in the literature from both controlled and randomized comparative trials of GnRH analogues and danazol (for review, see Shaw 1995). These trials have all confirmed the value of GnRH analogues for the treatment of endometriosis. Rapid and effective symptomatic relief is achieved with these agents, as well as a marked degree of resolution of the endometrial deposits in the majority of patients. However, for both symptomatic relief and the resolution of endometrial deposits, there is essentially no significant difference in comparative trials between GnRH analogues and danazol. However, patient acceptability and the profile of side-effects may be slightly in favour of GnRH analogues (Matta and Shaw 1987, Henzl et al 1988).

Side-effects of GnRH analogues include those which are predictable from induction of a pseudomenopause. These include hot flushes (in virtually all patients), headaches and, less commonly, atrophic vaginitis, vaginal dryness and reduced libido.

Dosage varies depending on the analogue used and its formulation, but regimens include: nafarelin 200 µg twice daily intranasally, buserelin 300–400 µg three times daily intranasally, goserelin 3.6 mg subcutaneous depot monthly, triptorelin 3.0 mg monthly, and leuporelin 3.75 mg intramuscular depot monthly.

Metabolic side-effects include (as in the menopause) increased excretion of urinary calcium. Over a 6-month period, there is a 3–5% loss in the vertebral trabecular bone density of the lumbar spine as assessed by dual energy X-ray absorptiometry. In most patients, the bone density changes induced following a 6-month course of therapy with GnRH analogues are reversed 6 months after return of ovarian function (Matta et al 1987, Henzl et al 1988). However, the implications of such changes in calcium homeostasis with prolonged and repetitive treatment with GnRH analogues are being further investigated. This has led to the development of protective 'add-back' regimens which reduce the symptomatic effects of the GnRH-agonist-induced hypo-oestrogenism, particularly the frequency of hot flushes and bone loss, but do not result in reduced therapeutic effectiveness on symptom relief or implant resolution. A recent meta-analysis of 15 studies assessing GnRH agonists with add-back with oestrogen and progestogen showed protection to the lumbar spine for up to 12 months following cessation of treatment (Sagsveen et al 2003).

A new series of GnRH antagonists are currently being developed, and these peptides contain multiple and complex substitutions of the GnRH molecule. There is little evidence on long-term use of GnRH antagonists in the treatment of endometriosis to date, and their structural complexity and costs may make substitution of GnRH antagonists for the current widely used GnRH agonists unlikely. However, orally administered non-peptide GnRH receptor antagonists are being developed and may present alternative therapies in the future.

Danazol

Danazol is an isoxazol derivate of 17- α -ethinyl testosterone. Due to its base structure, it has both androgenic and anabolic properties. Danazol was one of the first approved medical treatments for endometriosis. Its mechanism of action is complex and includes suppression of the hypothalamic–pituitary axis with interference in pulsatile gonadotrophin secretion and inhibition of the midcycle gonadotrophin surge, but with no change in basal gonadotrophin levels. It achieves direct inhibition of ovarian steroidogenesis by inhibiting several enzymatic processes and by competitive blockage of androgen, oestrogen and progesterone receptors in the endometrium. An increase in free testosterone occurs because of a reduction in sex-hormone-binding globulin, and this explains many of danazol's androgenic side-effects. The increase in free testosterone may also contribute to its direct action in inducing endometrial atrophy. The degree of endocrine changes described above is dose related.

In the treatment of endometriosis, danazol is administered in a dose range of between 400 and 800 mg daily, titrated to endeavour to induce amenorrhoea. In the case of mild-to-moderate endometriosis, there is highly effective symptomatic improvement in over 85% of cases.

Objective resolution of endometriotic lesions has been observed at post-treatment laparoscopic evaluation in between 70% and 95% of patients, depending upon the stage of the disease (Barbieri et al 1982). However, recurrence rates of up to 40% have been reported in the 36 months after completion of a course of danazol.

Danazol therapy should be commenced in the early follicular phase of the menstrual cycle. It is recommended that the patient should use additional barrier methods of contraception in order to avoid the drug being administered during early pregnancy, where continued use could lead to androgenization of a developing female fetus. The drug dosage should be related to the patient's clinical staging, response and severity of side-effects, starting with a dose of 400 mg/day in mild disease and 600–800 mg/day in moderate-to-severe cases for a recommended treatment course of at least 6 months.

Danazol is associated with side-effects related to its androgenic and anabolic properties. These include weight gain, acne, oily skin, fluid retention, muscle cramps, hot flushes, depression and mood changes. Less commonly, hirsutism, skin rash and voice deepening are noted. It is recommended that patients should discontinue treatment immediately if they develop hirsutism, a skin rash or deepening of the voice.

Metabolic side-effects include elevation of low-density lipoproteins, and reduction of high-density lipoproteins and cholesterol concentrations. In addition, changes in liver enzymes are noted, and danazol is contraindicated in patients with liver disease.

Gestrinone

Gestrinone is a synthetic trienic 19-norsteroid (13-ethyl-17- α -ethinyl-17-hydroxy-gona-4,10,13-triene-3-one). It has been shown in clinical trials to be another effective clinical treatment for endometriosis (Thomas and Cooke 1987). The

drug exhibits mild androgenic and antigonadotrophic properties. The combined effect is to induce progressive endometrial atrophy. Gestrinone has a high binding affinity for progesterone receptors; it also binds to androgen receptors but not to oestrogen receptors. The combined endocrine effect of gestrinone therapy is similar to that of danazol in that the midcycle gonadotrophin surge is abolished, although basal gonadotrophin levels are not significantly reduced, together with inhibition of ovarian steroidogenesis and reduction of sex-hormone-binding globulin levels. Gestrinone has a prolonged half-life and may be administered orally at a dosage of 2.5–5.0 mg twice weekly for a period of 6–9 months in patients with endometriosis. This dosage schedule effectively induces endometrial atrophy, with 85–90% of patients becoming amenorrhoeic within 2 months.

Gestrinone compares favourably with danazol in terms of both symptomatic relief and resolution of endometrial deposits (Mettler and Semm 1984).

The side-effects, occurring in up to 50% of patients, include weight gain, breakthrough bleeding, reduced breast size, muscle cramps and, uncommonly, hirsutism, voice change and hoarseness.

Aromatase inhibitors

Aromatase P-450 is the key enzyme for oestrogen biosynthesis, and catalyses the conversion of androstenedione and testosterone to oestrone and oestradiol. Aromatase activity is expressed inappropriately in endometriotic deposits and their eutopic endometrium, but not in the endometrium of normal women. Prostaglandin E₂ is a potent inducer of aromatase activity in endometriotic cells, and hence there is a link between repeated proliferation and inflammation within endometriosis deposits.

Limited data have been published on the use of aromatase inhibitors in endometriosis. A meta-analysis of 40 women from seven published case studies utilizing aromatase inhibitors in combination with progestogens, COCP or GnRH-A reported reduced mean pain scores and lesion size, and improved quality-of-life scores (Nawathe et al 2008). More data are needed to establish the efficacy and safety of aromatase inhibitors, and which combination of drugs produces the best results.

Other drug therapies tried or in development

A number of potential new drug therapies to treat endometriosis have been postulated, investigated in animals or are under development. These include progesterone antagonists, selective oestrogen receptor modulators and statins. However, scant, often only research data exist, and further data or modification of regimens to reduce side-effects would be necessary before they become clinically viable therapies.

In addition, research is underway to evaluate selective progesterone receptor modulators, selective oestrogen receptor β -agonists, angiogenesis inhibitors and immunomodulators/inflammatory modulators. It will be some considerable time before it is known if any of these approaches prove to be effective and tolerable as therapeutic options in the treatment of endometriosis.

Surgical Treatment

Many forms of severe endometriosis do not respond to drug treatment, including deep-seated invasive disease, endometriomas, extrapelvic endometriosis of the bladder and bowel, or within surgical scars. In these instances, surgery may be required to relieve the symptomatology and effect a longer term cure.

Conservative surgery

Endometriotic deposits may be excised, destroyed by electrocautery, or evaporated utilizing carbon dioxide or KTP/YAG lasers or argon beam.

With the increasingly widespread availability of laparoscopic expertise, improved instrumentation and experience of laser technology, minimal access surgery is becoming a more popular treatment option. There have been few appropriately conducted randomized trials, but one small double-blind placebo-controlled study measured pain relief following laser ablation and/or laparoscopic uterosacral nerve ablation or placebo (no treatment). At 6 month follow-up, 53% of those treated with laser compared with only 23% from the placebo diagnostic laparoscopy group had improvements in symptoms (Sutton et al 1994). It was of interest that in minimal disease, only 38% of women had a reduction in pain. Therefore, this approach appeared to be more effective in reducing pain symptoms in women with more severe disease.

Sutton et al (1997) published the results of a longer term follow-up of this cohort of patients. Sadly, 1 year after the initial treatment, 44% had recurrence of pain requiring additional treatment. The reasons for failure of the surgical approach may result from missing lesions, incomplete destruction and, of course, recurrence of the disease.

An alternative approach to ablation of lesions is excision. Advocates of this approach argue that excision is the only way to ensure complete treatment because it may be difficult to determine the depth of the implant. Local excision can achieve good results in terms of pain reduction — 67% improvement up to 12 months (Wykes et al 2006) — but another study reported a high reoperation rate with longer term follow-up of 46% at 5 years and 55% at 7 years (Shakiba et al 2008) (see Figures 33.15 and 33.16).

Laparoscopic uterosacral nerve ablation

The uterosacral ligaments are a commonly affected site in patients suffering with endometriosis, and infiltration of endometriotic deposits results in invasion, inflammation and fibrosis of the anterior extension of the inferior hypogastric nerve, the uterovaginal plexus (or Lee-Frankenhauser plexus). Ablation of the uterosacral ligaments, forming two small craters, can be performed at the time of laparoscopy. The risks of the procedure are haemorrhage from a vessel within the uterosacral ligaments and damage to the ureter, which needs to be identified before laser treatment commences.

In a double-blind randomized controlled study, the addition of laparoscopic uterosacral nerve ablation to laparoscopic laser vaporization of endometriotic lesions alone was

Figure 33.15 Left uterosacral nodule.

Source: Overton C, Davis C, McMillan L, Shaw RW 2007 *An Atlas of Endometriosis*, 3rd edn. Informa Healthcare, London.

not found to improve pelvic pain responses (Sutton et al 2001). This procedure should not be performed if the uterosacral ligaments have a normal appearance, whilst excision of deep infiltrating lesions on the uterosacral ligament seems to be beneficial.

Radical surgery: hysterectomy and oophorectomy

Radical surgery is reserved for those patients with severe symptoms, where there is no desired fertility potential and especially when other forms of treatment have failed. Total abdominal hysterectomy and bilateral salpingo-oophorectomy are performed along with resection of any endometriotic lesions as completely as possible. As the majority of these patients are relatively young, hormone replacement

therapy should be commenced but kept to a minimum to control oestrogen-deficiency symptoms, as a small percentage of those patients may develop a recurrence of endometriosis when on such oestrogen replacement.

Combined oestrogen–testosterone implants may minimize the risk of recurrence as well as offering the beneficial effects of the androgens in maintaining libido in young women who are sexually active. However, no data exist from randomized trials to define if one particular hormone replacement therapy regimen is superior to others.

Surgical treatment of endometriomas

The definitive treatment of the typical endometrioma is the surgical release of the adhesions and fibrosis at the site of invagination, and the eversion of the invaginated cortex. Simply puncturing and draining the endometrioma, whether this is followed by GnRH agonist therapy or not, has no beneficial effects in the long term (Vercellini et al 1992). Medical treatment is highly effective for the destruction of active implants located on the surface of the normal ovarian cortex. However, when a definite endometrioma is present, surgery is necessary. This can be performed laparoscopically for smaller endometriomas using laser destruction. With endometriomas larger than 3 cm in diameter, treatment may be facilitated to enable laparoscopic surgery if, following initial drainage, patients are pretreated for 3 months with a GnRH agonist prior to laser ablation (Donnez et al 1990).

On the other hand, fibrotic larger endometriomas have a thickened capsule which is more likely to be removed effectively by excisional techniques.

In many instances, however, because of other associated extensive adhesions and fixity of ovaries on to other structures, a laparotomy rather than a laparoscopy may be necessary.

Whatever the surgical approach, be it minimal access or open laparotomy, if dense and extensive adhesions are present at the time of original surgery, it is likely that such patients will have recurrence of adhesions with attendant problems of fixity of the ovary following such approaches (Shaw et al 2001).

Recurrent Endometriosis

The natural course of the disease remains a mystery. It has been suggested that the disease is only progressive in one-third of cases, whilst in the remainder, the endometriosis remains in a steady state or eventually even resolves spontaneously.

After medical suppression of the disease or surgical destruction of all visible deposits, residual viable (microscopic) implants can regenerate once ovarian function is re-established. In other cases, new disease develops at new sites, perhaps indicating the potential for an entire 'field change' within the pelvic peritoneum. The degree of differentiation of a lesion may also correlate with persistence of disease following medical therapy. Two-thirds of lesions that were most highly differentiated disappeared following 6 months of medical therapy, whilst three-quarters of poorly differentiated lesions persisted (Schweppe 1984).

However, as far as therapeutic options are concerned, there is no essential difference between primary and recurrent endometriosis. The choice of treatment in a patient with recurrent disease is not determined by the manifestations of the disease as such, but more by the extent of distortion of the pelvic anatomy and the severity of

symptomatology. In many instances, repeat medical therapy or repeat conservative surgery is appropriate, but when there are severe symptoms and repeated recurrence, a radical surgical approach may be the patient's best option to achieve longstanding relief of pain and other symptoms.

KEY POINTS

1. Endometriosis is one of the most common gynaecological conditions and is present in 10–25% of women presenting with gynaecological symptoms.
2. Endometriosis is most commonly found inside the pelvis, but rarely it has been described in sites such as the urinary tract, bowel, lungs and umbilicus.
3. The growth of endometriotic tissue depends on oestrogen; thus, endometriosis occurs almost exclusively in the reproductive years, with a peak incidence between 30 and 45 years of age.
4. The theories of aetiology of endometriosis include Sampson's theory of retrograde menstruation and implantation, and Meyer's theory of transformation of coelomic epithelium. Genetic predisposition and immunological factors are also thought to be important in rendering individuals susceptible to the disease.
5. The peritoneal fluid in women with endometriosis contains higher concentrations of more active macrophages and prostaglandins than in normal women. These factors may be important in explaining the link between infertility, pain and endometriosis.
6. Endometriosis that is associated with tubal and ovarian damage and the formation of adhesions can compromise fertility. The link between mild endometriosis and infertility is more controversial.
7. Suppression of ovarian function is not effective at improving fertility in women with endometriosis.
8. The best means to diagnose endometriosis is by direct visualization at laparoscopy or laparotomy, with histological confirmation where uncertainty persists.
9. Non-invasive tests are being developed, and additional investigations are of value in diagnosing extrapelvic disease.
10. The typical blue–black peritoneal endometriotic lesion is described as a 'powder burn'. Recently, non-pigmented lesions and red lesions have been described together with many other visual appearances now recognized as hallmarks of the disease process.
11. The medical treatment of endometriosis involves suppressing oestrogen–progesterone levels to prevent cyclical changes and menstruation. Treatments include progestogens, gestrinone, danazol and gonadotrophin-releasing hormone analogues.
12. Induction of complete amenorrhoea is the key to successful control of pain symptoms.
13. The surgical treatment of endometriosis is either minimally invasive (e.g. laparoscopic diathermy or laser vaporization) or radical (e.g. total abdominal hysterectomy or bilateral salpingo-oophorectomy). Extrapelvic and deep-seated endometriosis invariably requires a surgical approach.
14. The performance of laparoscopic uterosacral nerve ablation where the uterosacral ligaments appear normal provides no added benefit in reducing pain levels.
15. The natural course of the disease is not clearly defined. However, in perhaps one-third of cases, the disease is progressive, whilst in the remainder, the disease remains in a steady stage or may even resolve spontaneously. For many patients, the disease is one of recurrent episodes of treatment cycles and recurrence throughout reproductive life.
16. There seems to be no justification to treat minimal-to-mild endometriosis where infertility and not pain is the predominant symptom. Such cases are best assessed for infertility treatment options based on the woman's age, duration of infertility and the presence/absence of other infertility factors.
17. Classification systems are subjective and correlate poorly with the severity of pain symptoms. They may help to determine the prognosis of infertility outcomes.

CERVICAL CANCER	509	KEY POINTS	519
ENDOMETRIAL CANCER	514		

Introduction

Epidemiology is the study of disease in populations as opposed to individuals. Its scope ranges from description of the incidence and mortality from disease at a national level, through analytical studies of disease causation, to interventions leading to disease prevention and mortality reduction. Epidemiology has made significant contributions to our understanding of the causes and control of gynaecological cancers. Human papilloma virus (HPV) is the primary cause of cervical cancer, but requires cofactors to cause malignancy. Obesity, nulliparity and use of unopposed oestrogens are major risk factors for endometrial cancer. Oral contraceptives are highly protective for ovarian cancer. Screening programmes have resulted in a substantial reduction in cervical cancer. Introduction of vaccination against HPV 16 and 18 in conjunction with established screening programmes is expected to reduce the incidence of cervical cancer by an additional 60% (allowing for incomplete coverage), and to have a substantial impact on vaginal (80%) and vulval (40%) cancers.

General Overview

Globally, breast cancer and cancer of the cervix are the two most common female malignancies. However, both ovarian and endometrial cancer rank in the top 10 female malignancies. Cervical cancer is most common in developing countries, while cancer of the uterine corpus and ovarian cancer have higher incidence in industrialized countries. Indeed, in the presence of cervical screening, these cancers are more common than cervical cancer in most Western countries. Table 34.1 provides an overview of age-standardized incidence and mortality rates of these three gynaecological cancers around the world. Other gynaecological cancers (i.e. cancers of the vulva and vagina) are relatively rare in all parts

of the world. The age-standardized rates are less than one per 100,000 in most countries (Curado et al 2007).

The variation in the rates of gynaecological cancers around the world is enormous (Table 34.1). Cervical cancer rates in East Africa are 12 times greater than in West Asia (the Middle East). The rates for cancer of the uterine corpus are nearly 10 times higher in North America than in West Africa, and ovarian cancer is two and a half times more common in Northern Europe than in Middle Africa. Some, but certainly not all, of these variations can be explained in terms of differences in lifestyle and public health interventions.

Cervical Cancer

The cervical epithelium is composed of two distinct cell types. The ectocervix is covered by non-keratinized squamous cells similar to those of the lining of the vagina. The endocervical canal is covered by columnar cells of the same origin as those of the endometrium. Cervical cancers initiate in the region where these two cell types meet — the squamo-columnar junction. There are three main types of cervical cancer (squamous, adenocarcinoma and adenosquamous carcinoma), with squamous cell carcinoma being the most common. It used to be said that this accounted for approximately 90% of all cases of cervical cancer. However, more recent data show that the proportion of cervical cancer that is adenocarcinoma or adenosquamous carcinoma has doubled, particularly in younger women. Squamous cell carcinoma now only accounts for approximately 75% of all cases of cervical cancer. The reason for the increasing proportion of adenocarcinoma seems to be three-fold: adenocarcinoma really is becoming more common, having been very rare; due to the introduction of mucin staining and greater awareness of adenocarcinoma, it is being reported more often on pathology reports; and cytological screening is more able to detect precancerous squamous lesions than

Table 34.1 Age-standardized rates (per 100,000 women-years) for cancer of the cervix, corpus uterus and ovary (world standard population)

Region	Cervix		Corpus uterus		Ovary	
	Cases	Deaths	Cases	Deaths	Cases	Deaths

precancerous glandular (adeno) lesions, and thus the relative incidence of the two types of cancer has changed (Sasieni et al 2009).

Invasive cervical cancer is preceded by precancerous neoplasia variously referred to as high-grade squamous intraepithelial lesion, cervical intraepithelial neoplasia (CIN) or carcinoma *in situ* (CIS). Epidemiological studies have focused not only on invasive cancer, but also on the more common preinvasive disease. A similar preinvasive phase has also been identified for adenocarcinoma (or adenocarcinoma *in situ*).

Descriptive epidemiology

Cervical cancer is the second most commonly diagnosed cancer in women. Worldwide, it is estimated that there are approximately half a million new cases of cervical cancer each year, accounting for approximately 12% of all female cancers (Garcia et al 2007). The cumulative incidence rate up to 74 years of age (assuming no prior death) ranges from 5% in parts of Latin America to approximately 0.5% in parts of the Middle East and Finland. In most European countries, it is under 2% (Curado et al 2007). Cervical cancer is also extremely common in sub-Saharan Africa, but African incidence data are unreliable, particularly for older women.

The incidence of cervical cancer in most countries has decreased significantly since the 1960s. In the UK, mortality from cervical cancer has been declining since 1950. The difference between mortality rates in 1950–1952 compared with 2005–2007 varies with age, from an extraordinary 85% reduction in women aged 55–64 years to a more moderate 15% reduction in women aged 25–34 years. Figure 34.1 shows the age-specific mortality rates for cervical cancer in the UK since 1971. It is seen that the greatest decreases have been in older women (aged ≥ 65 years), and that the increasing rates in younger women between 1970 and 1985 reversed in the 1990s.

The differing cervical cancer mortality and incidence trends by age can be examined by birth cohort analysis in addition to analysis by year of death. Plotting the rate of disease against age for women born in different 5-year periods yields a series of curves, approximately parallel, but with some higher than others. In other words, women born at one time might be at relatively high risk of cervical cancer in their 20s and 30s, and remain at relatively high risk through their 40s, 50s, 60s and 70s. The authors' understanding of this effect is that there is an underlying characteristic of increasing rate of disease with age, but the level is determined by environmental exposure (to a sexually transmitted agent) in the late teens and 20s. So, for example, for women born at the end

Figure 34.1 Age-specific mortality rates for cervical cancer, UK 1971–2007.

of the 19th century or around 1920, cervical cancer mortality was higher throughout their lives than for previous and subsequent birth cohorts. These two cohorts of women with increased risk would have become sexually active around the times of World War I and World War II.

The level of environmental exposure will be determined by social norms and will vary between ethnic groups and over time. Modelling shows that the idea that incidence and mortality rates can be modelled by age and cohort effects works well until the 1980s. However, more recent data require the addition of age-specific time trends corresponding to a beneficial effect of screening, particularly in younger women, to provide a satisfactory model (Sasieni and Adams 2000). From a public health perspective, it is important to note that women born in the 1960s are at three- to four-fold higher risk of cervical cancer compared with women born in the 1930s.

Risk factors

Evidence for an association between cervical cancer and sexual activity dates back to 1842, when Rigorni-Stern published data showing that whereas married women were more likely to die of cancer of the uterus (predominantly cervix) than breast cancer, nuns very rarely died of cancer of the uterus. Since then, the epidemiological evidence suggestive of a sexually transmitted agent causing cervical cancer has grown steadily. Traditional risk factors include the number of sexual partners and age at first sexual intercourse. The behaviour of men is also important, as shown by increasing risk in women with just one partner according to the number of partners of their husband (Buckley et al 1981). More recently, the sexually transmitted agent has been identified as certain types of HPV. The evidence that the relationship between HPV infection and cervical cancer is causal is overwhelming (Bosch et al 2002). Several large studies have been carried out to determine the prevalence of HPV in cervical cancer and precancerous lesions. Over 90% of cervical cancers have been found to include HPV DNA (Smith et al 2007), and when full adjustment for tissue adequacy and a range of polymerase chain reaction primers are used, the

estimates rise to almost 100% (Walboomers et al 1999). Several studies have shown that HPV-negative women have an extremely low risk of CIN 3 or cancer (Bulkman et al 2007, Cuzick et al 2008a, Dillner et al 2008). Furthermore, a recent study (Sankaranarayanan et al 2009) found no cancer deaths among 30,000 HPV-negative women in the subsequent 8-year period.

There are over 100 types of HPV, and only some of these infect the anogenital region. These can be split into low-risk types, which cause genital warts, and high-risk types, which can lead to cervical cancer. Types 16 and 18 are strongly associated with cervical cancer; other types including 31, 33, 35, 39, 45, 51, 52, 56, 58 and 66 are associated with a more moderate elevated risk. Table 34.2 details the prevalence of the most common high-risk types of HPV in women with normal cytology, precancerous cervical lesions and invasive cervical cancer in the UK and worldwide.

It has been estimated that HPV is a very common sexually transmitted infection worldwide, with the majority of people being exposed to the virus by 30 years of age. Most infections with high-risk types are transitory and harmless. In a minority of women, the infection may become persistent and lead to high-grade cervical lesions with a potential for progression to cancer. Immune factors are certainly associated with persistence, but are poorly understood. Similarly, it is largely unknown why some women with persistent infection develop cervical cancer whereas others do not.

Other risk factors are less clear cut. Smoking is generally found to be associated with cervical cancer, but it is difficult to disentangle the confounding caused by the sociological link between smoking and increased number of sexual partners. Nevertheless, the body of evidence available suggests that smoking increases the risk of cervical cancer two- to three-fold by reducing the local immune response to HPV (Kapeu et al 2009). The association between oral contraceptive use and cervical cancer is also confounded by sexual behaviour; however, a large pooled analysis including 24 studies found that women who had used oral contraceptives for 5 years or more were at almost double the risk of cervical cancer compared with women who had never used oral contraceptives. This risk declines after the use of oral contraceptives is stopped; within 10 years, the risk is similar to non-users (Appleby et al 2007). High parity and young age at first full-term pregnancy have, independently, been found to increase the risk of invasive cervical carcinoma, and this association remains after adjusting for other reproductive factors. Women with seven or more pregnancies are at approximately 78% greater risk than women with one or two pregnancies. It is estimated that cervical cancer could be reduced by 30% in developing countries if parity and age at first intercourse were the same as in developed countries (International Collaboration of Epidemiological Studies of Cervical Cancer 2006). Previous exposure to sexually transmitted diseases, in particular *Chlamydia trachomatis* and herpes simplex virus type 2, also increases the risk of cervical cancer, even after adjusting for HPV infection (Bosch and de Sanjose 2007).

Immunosuppression certainly conveys an increased risk of cervical cancer, as shown in studies on renal transplant patients receiving immunosuppressive drugs (Birkeland et al 1995) and on women who are human immunodeficiency virus (HIV) positive (Grulich et al 2007). It seems likely that diet plays a role in the immune response to HPV, but studies

Table 34.2 High-risk human papilloma virus (HPV) prevalence in women with normal cytology, precancerous cervical lesions and invasive cervical cancer

^eWalboomers et al (1999).

on diet and cervical cancer have found little evidence for a strong effect of intake of fruit and vegetables on the risk of cervical cancer (IARC Handbooks of Cancer Prevention 2003). It has been shown recently that cervical neoplasia (including CIS) exhibits familial clustering and that the strength of association increases with increasing genetic relatedness (Magnusson et al 1999). Independently, several groups have found an association between certain human leukocyte antigen class II antigens and cervical neoplasia. However, much more remains to be done in understanding the factors that determine why some women infected with oncogenic HPVs develop cervical cancer but the vast majority do not.

Natural history

There are few data from studies that directly observe the natural history of cervical cancer development because it is generally felt to be unethical not to treat precancerous cervical disease. The situation is further complicated by the possibility that the process of taking a biopsy, required for definitive diagnosis of disease, may affect the natural history by stimulating regression. Therefore, most of what is known of the natural history of cervical precancer is derived from the follow-up of women with cytological abnormalities and the study of the incidence and prevalence of cervical lesions. There is one exception — cervical CIS in Auckland, New Zealand between 1965 and 1974. Women with CIS were not treated. A judicial inquiry in 1988 concluded that this practice was unethical, but allowed the histological and other material to be used for further research. Two studies have been published using this data (McIndoe et al 1984, McCredie et al 2008), with the most recent paper including over 25 years of follow-up (McCredie et al 2008). This study provides the most direct estimates available of the rate of progression from CIS to invasive cancer; the results show that approximately 30% of CIS progress to cancer within 30 years.

For the vast majority (estimated as well over 95%) (Walboomers et al 1999) of cervical cancers, the first step is exposure to one of the oncogenic HPVs. The time from infection to the development of invasive cancer is thought to be many years; typically between 10 and 40. Longitudinal studies on young women show that the majority of HPV infections are transient (Moscicki et al 2004) and that the virus is indeed sexually transmitted (Burk et al 1996). Persistence of infection has been shown to be associated with the development of cervical lesions (Ho et al 1995). It is generally believed that one of the key steps in the development of cancer is integration of the viral DNA in the host genome (Das et al 1992), although some carcinomas only have episomal viral DNA (Cullen et al 1991).

Cervical neoplasia appears to constitute a disease continuum ranging from CIN grades I to III, to microinvasive cancer and, finally, fully invasive cancer. More recent evidence shows that CIN I is frequently not associated with HPV infection and may not be part of the continuum. However, histology is not currently able to distinguish CIN I associated with oncogenic HPV infection from CIN I without HPV DNA. The histological report of HPV infection is based on morphological features, and is not particularly tightly correlated with the presence of oncogenic HPV DNA.

Follow-up studies of women with CIN have found that approximately 60% of CIN I regresses compared with approximately 33% of CIN III; 11% and 22% of CIN I and II, respectively, progressed to CIN III (Östör 1993). Modelers find that regression is more common in younger women, and that three-quarters of CIN in women under 35 years of age will regress (van Ballegooijen et al 1997). They estimate the mean duration of CIN to be 12 years, and that the time from HPV infection to CIN is between 1 and 10 years. Although the details of progression and regression are largely speculative, it is clear that, at most, approximately one-third of high-grade CIN will progress to cancer over approximately 15 years and that the majority of CIN I will regress.

CIN III rates rise rapidly before 30 years of age. Rates then decrease, rather more slowly, being at approximately half their peak by 40 years of age and just 10–20% of their peak by 50 years of age (Office for National Statistics 2006). The extent to which published CIN III rates reflect the prevalence of an untreated condition and the extent to which they mirror incidence is not completely clear.

Prevention and screening

Prevention of cervical cancer could be approached in several ways. Strategies aimed at promoting safe sex (use of condoms, particularly with an occasional partner), delaying the age of first sexual intercourse and reducing the number of women who smoke are only likely to have modest effects on cervical cancer rates. However, if successful, they would also have additional health benefits in terms of control of sexually transmitted diseases (including chlamydia with the resultant pelvic inflammatory disease), reduction in teenage pregnancies and reduction in heart disease and lung cancer, respectively.

The impact of vaccination on rates of cytological abnormalities, CIN III and invasive cancer will not be seen for at least 12–16 years after vaccination is rolled out. It is possible that, in 30 years time, prevention of cervical cancer may be achievable by vaccination of teenage girls (within a well-organized high-coverage programme) against a large subset of HPV oncogenic types. Until that time, the most likely route to reducing the morbidity associated with cervical cancer is through the detection and treatment of precancerous cervical lesions. Screening by cytological analysis of cervical smears has proven to be an effective means of reducing the incidence of cervical cancer in many industrialized countries. It satisfies most of the criteria that should be considered before introducing a public screening programme. Cervical screening programmes were set up with the intention of preventing cervical cancer. They also have the additional benefit of reducing mortality from cervical cancer by diagnosing occult invasive tumours at an early stage when they are more treatable. Cervical screening was offered to women well before its effectiveness had been demonstrated. By the time that people considered the possibility of evaluating cervical screening in a randomized controlled clinical trial, the indirect evidence of the benefits of such screening made a trial in which some women were deprived of screening unethical in a setting where screening is already routine. In the absence of randomized trials, researchers sought evidence from population trend studies and studies that looked at screening at the individual level rather than in populations. The individual-level studies have mainly been carried out as case-control studies, comparing the screening experience of women diagnosed with or dying from cervical cancer with that of healthy women. Ideally, case-control and population trend studies should be interpreted together. The fact that women with cervical cancer are less likely to have been screened than healthy women could be confounded, to some extent, by socioeconomic status and attitudes to healthy lifestyles. Women who do not attend for screening may be at greater risk than those who attend even if screening is useless, simply because they are more likely to smoke, to have a poor diet and to be exposed to oncogenic HPVs. Taken together, however, one sees a picture in which overall

cancer rates are falling and women who have been screened are less likely to develop cancer than those who have not.

Estimates of the sensitivity of cytology are available from studies in which a large number of women with negative cytology have colposcopy. Ideally, colposcopy should be offered to all women, but this would be expensive and taking a biopsy from all women would be unethical. Many studies comparing two or more screening tests (such as cytology, HPV testing, direct visual inspection) offer colposcopy to all women who are positive on one or more of the screening tests. From such studies, the sensitivity of cytology for high-grade CIN is found to be between 50% and 75% (Nanda et al 2000, Cuzick et al 2006). However, most cases of missed CIN 3 would not become cancerous within 5 years. It is for this reason that screening is recommended, in most countries, to start around the age of 20 years and continue at regular intervals (of between 3 and 5 years) up to the age of 65 years.

There is now sufficient evidence that testing for HPV infections with a primary screening tool can reduce cervical cancer incidence and mortality rates (IARC Monographs 2007). Although HPV testing has high sensitivity (>90%), it is, on average, 6% less specific than cytology (Cuzick et al 2008b). This leads to a higher number of women being referred to colposcopy with no visible lesions. This is especially important in women under 30 years of age, in whom transient HPV infection and cervical lesions are most common. In many high-resource settings, HPV testing is being used in the triage of women over 30 years of age with borderline or mild smears. However, in low-resource settings where organized cytology is not feasible, introduction of HPV testing with subsequent ablative treatment for those women that are positive is an attractive alternative (Sankaranarayanan et al 2009). The introduction of HPV testing to the screening programme would allow the screening interval to be extended (Bulkman et al 2007, Cuzick et al 2008b, Dillner et al 2008).

Human papilloma virus vaccines

Prophylactic HPV vaccines are L1 virus-like particles (VLPs) in which the surface L1 protein is made to aggregate into particles, mimicking the virus in antigenic respects but not containing the viral DNA. VLPs have been shown to induce a high titre of in-vitro neutralizing antibodies and to protect against experimental challenge with homologous virus in animal models. As VLPs do not contain any viral genes, they are non-infectious and non-oncogenic. To date, two vaccines are commercially available (Cervarix™ and Gardasil™); both are licensed to be applied in three doses within 6 months. Both preparations immunize against HPV 16 and 18, and Gardasil also immunizes against HPV 6 and 11. Results from a number of randomized controlled trials have been published to date. The phase III trials are designed to evaluate the endpoint of CIN 2/3 associated with the HPV types included in the vaccine (Harper et al 2006, Garland et al 2007, Paavonen et al 2007). The smaller phase II trials were powered primarily to evaluate protection from infection by the vaccine types (Villa et al 2005, Mao et al 2006).

There is no evidence that vaccination is effective against an HPV infection that is already present at the time of vaccination (i.e. vaccines do not induce HPV clearance or reduce

progression) (Hildesheim et al 2007). This is important when interpreting the results from clinical trials. There are three main types of analysis for efficacy studies. The according-to-protocol analysis (ATP) only included those women who were HPV negative at enrolment, received all three vaccine doses and remained HPV negative up to the final dose. The modified intention-to-treat (MITT) analysis included study participants who received at least one dose of vaccine, and who were negative for relevant HPV types at enrolment (Cervarix studies) or were randomly assigned to study group irrespective of their baseline HPV status (Gardasil studies). Finally, the intention-to-treat analysis included all randomized subjects.

The vaccine trial subjects differed in age (mostly aged 15–26 years) from the recommended age at vaccination (10–14 years). As younger women are less likely to be infected with HPV at the time of vaccination, the ATP or MITT analysis will more closely reflect the efficacy that one would expect to observe in individuals vaccinated at 10–14 years of age. Vaccine efficacy results by analysis type are detailed in Table 34.3. Overall, HPV vaccines are over 95% effective against vaccine HPV types in HPV-naïve women. Recent results from the PATRICIA trial suggest that this vaccine also confers a high degree of cross-protection against other HPV types (specifically HPV 31, 45 and 33), and that the overall efficacy against CIN 2 or worse associated with any HPV type in the ATP analysis is 70% (Paavonen et al 2009).

HPV vaccination has been approved and is being rolled out in over 90 countries worldwide. In England, vaccination was introduced in 2008–2009 to girls aged 12–13 years, with a catch-up campaign for girls up to 17–18 years of age.

Endometrial Cancer

Most cancers of the uterine corpus are adenocarcinomas of the endometrium. Sarcomas of the myometrium (muscle) are rare and are not considered in this chapter. Endometrial cancer comprises approximately 4% of all female cancers worldwide (Bray et al 2005). Incidence rates of endometrial cancer in Western countries are three to eight times as

great as mortality rates, reflecting the high cure rate for these cancers (Table 34.1). In fact, 5-year survival for endometrial cancer patients relative to the general population is approximately 70% (Garcia et al 2007). Endometrial cancer is rare in premenopausal women, but becomes relatively common in postmenopausal women; in 2006, the incidence of endometrial cancer in England was 14 per 100,000 in women aged 45–49 years, compared with 29 per 100,000 in women aged 50–54 years. In recent years, endometrial cancer rates have been substantially greater in women over 60 years of age compared with women aged 50–59 years, whereas the rates were similar in the past (Figure 34.2A). Incidence rates are highest in North America; up to 10 times higher than in parts of Africa and almost double those in Northern Europe (Table 34.1). Data from the US Cancer Statistics 2001–2005 show that incidence rates are higher among US Whites (23.5 per 100,000) than Blacks (19.1 per 100,000) (US Cancer Statistics Working Group 2009).

When studying trends in endometrial cancer, it is important to look at 'cancer of the uterus, site not specified' since, in many countries, the majority of those cancers will have originated in the endometrium. In both England (Sasieni et al 1997) and the USA (Ries et al 2001), mortality rates fell steadily and substantially (approximately 60%) between 1950 and 1990. More recent UK trends are shown in Figure 34.2B. Incidence rates in women over 55 years of age have been increasing in the UK and across Northern Europe. In contrast, rates in premenopausal women have been declining (Bray et al 2005). The observed trends in younger women have been attributed to the widespread use of the combined oral contraceptive pill (COCP), while the increasing incidence observed in older women is believed to be linked to the increased prevalence of obesity. Interpretation of trends is complicated by the prevalence of women who have had a hysterectomy, since women without a uterus are obviously not susceptible to uterine cancer.

Risk factors

The main aetiological factors for endometrial cancer are obesity, hormonal levels and reproductive history.

Table 34.3 Efficacy of two prophylactic vaccines against human papilloma virus type 16/18-related cervical intraepithelial neoplasia (CIN)

		No. of subjects			Efficacy against 16/18-related lesions*		
Vaccine	Study	Vaccine	Placebo	Endpoints	ATP	MITT	ITT
Gardasil Quadrivalent (16/18/6/11)	Merck 007 (Villa et al 2005)	235	233	CIN 1–3, AIS	100% (<0–100)	100% (31–100)	NR
	FUTURE I (Garland et al 2007)	2241	2258	CIN 1–3, AIS	100% (94–100)	98% (92–100)	55% (40–66)
	FUTURE II (2007)	6087	6080	CIN 2/3, AIS	98% (86–100)	95% (85–99)	44% (26–58)
Cervarix Bivalent (16/18)	GSK 001/07 (Harper et al 2006)	481	470	CIN 2/3	100% (8–100)	NR	NR
	PATRICIA (Paavonen et al 2007, 2009)	7788	7838	CIN 2/3	98%* (90–100)	90% [†] (53–99)	30.4%* (16–42)

ATP, according to protocol; MITT, modified intention to treat; ITT, intention to treat; NR, not reported.

95% confidence intervals, except 97.9%[†] and 96.1% confidence intervals for PATRICIA.

Figure 34.2 Age-specific (A) incidence and (B) mortality rates for corpus uterine cancer (including uterine unspecified), UK 1971–2007.

Obesity is consistently found to be associated with endometrial cancer in both case-control and cohort studies. Due to the high prevalence of obesity in many populations, is likely to be responsible for a significant proportion of cases of endometrial cancer. Typically, studies report a two- to three-fold risk of endometrial cancers associated with obesity (Schouten et al 2004), but some studies have found much stronger effects (Weiderpass et al 2000). Obesity is likely to affect cancer rates by increasing the level of circulating oestrogens, particularly in postmenopausal women. This occurs due to increased conversion of androstenedione to oestrogen, and decreased levels of sex-hormone-binding globulin (Cook et al 2006). There is some evidence that greater upper body fat, as opposed to overall obesity, might be a better indicator of the risk of endometrial cancer, and that waist circumference and waist:hip ratio could be a better predictor of risk than body mass index (BMI; Xu et al 2005). Diabetes has been associated with a two-fold increased risk of endometrial cancer (Friberg et al 2007). Although it is difficult to distinguish between the risks associated with increased body weight and the risks of diabetes *per se*, there is evidence that hyperinsulinaemia increases the risk of endometrial cancer (Lukanova et al 2004).

Oestrogens are the primary stimulation for endometrial proliferation. In premenopausal women, oestrogens are counteracted by progestagens; however, in postmenopausal women, they go unopposed. Any state that reduces the exposure of uterine tissue to oestrogen or oestrogen-like substances reduces the risk of endometrial cancer, and inversely, any medical condition that results in high levels of endogenous oestrogens increases the risk (i.e. polycystic ovaries, oestrogen-secreting ovarian tumours). Pregnancy and parity reduce the risk of this cancer by 30% for the first birth and by 25% for each successive birth. The use of the COCP reduces the risk by 10% for each year of use, so that there is approximately a 65% reduction with 10 years of use. The protective effect of the COCP lasts for at least 15 years after last use (Pike et al 2004). Oestrogen replacement therapy has been consistently found to be associated with an increase in endometrial cancer. A meta-analysis estimated a relative risk of 2.3 in ever-users compared with never-users, and

found that the risk remains elevated for several years after cessation of use (Grady et al 1995). The risk appears to increase both with increasing duration of use and increased dose of oestrogen, with a relative risk of 10 associated with 10 years of use (Grady et al 1995). Newer hormone replacement therapy preparations including a progestogen either as a continuous combined replacement or used sequentially for the last 10 days per month cause minimal, if any, increased risk of endometrial cancer (Beresford et al 1997). The oestrogen receptor modulator hormone used in the treatment and prevention of breast cancer, tamoxifen, has been shown to increase the risk of endometrial cancer two- to three-fold (Cuzick et al 2003). Physical activity and smoking have been shown to decrease the risk of endometrial cancer. Physical activity independent of body weight has been shown to reduce the risk of endometrial cancer by 23% (Voskuil et al 2007). Smoking has consistently been associated with a decreased risk of endometrial cancer; this effect might be linked to the fact that smokers metabolize oestrogens into less harmful metabolites than non-smokers. A recent study (Viswanathan et al 2005) found that smoking reduced the risk of endometrial cancer by 30–40% among current and past smokers, and that the effect was greater in those who had been smoking for longer.

Women with Lynch syndrome (hereditary non-polyposis colorectal cancer) are at very high risk of endometrial cancer from 40 years of age. The risks differ depending on the affected gene, but lifetime risk is thought to be between 40% and 60% (Meyer et al 2009). For this reason, most women with Lynch syndrome will have a prophylactic hysterectomy between 40 and 50 years of age.

Prevention and screening

Primary prevention of endometrial cancer should be aimed at weight loss and careful monitoring of women taking oestrogen-only hormone replacement therapy, both of which would have net benefits on woman's health. Screening is unlikely to have a role in the foreseeable future. The COCP reduces the risk of endometrial cancer and the protection lasts for at least 15 years after use. Since the COCP

increases the risk of breast cancer, the overall risk benefit is not likely to be favourable in women over 40 years of age.

Ovarian Cancer

Ovarian cancer is the sixth most common type of cancer and the sixth most common cause of cancer mortality in women in the developed world (Garcia et al 2007). Survival is very poor, except when the tumour is detected early, which is rare in most countries. Overall 5-year survival statistics estimate survival to be 46% in the USA (Horner et al 2008) and 39% in England (Office for National Statistics 2008). However, when the cancer is detected at an early stage, 5-year survival increases to over 70%. Approximately 90% of ovarian cancers are adenocarcinomas of the epithelium, but germ cell tumours are the most common histological type in women under 30 years of age.

Descriptive epidemiology

Variation in the rates of ovarian cancer around the world is less marked for ovarian cancer than for other gynaecological cancers (Table 34.1). The highest rates are found in Northern Europe and in White women in North America and Western Europe. Similarly, rates tend to be lower in most Asian countries, but women of Japanese and Chinese descent in the USA have rates that are higher than in their countries of origin.

Trends in ovarian cancer in England and Wales differ by age. Mortality rates in premenopausal women have fallen considerably since the 1970s (Figure 34.3). By 1999, the rates in women aged 30–44 years were just half of what they had been in 1970. The picture for older women is dramatically different. Rates in women over 65 years of age have increased, and by 2006, the rates in women over 65 years of age were over 30% greater than they were in 1971. The incidence of ovarian cancer is only slightly greater than the mortality rates, reflecting the poor cure rate for this disease. Consequently, trends in incidence are similar to the trends in mortality. Recently, however, survival has improved substantially due to a combination of earlier detection and the use of platinum-based chemotherapies (Kitchener 2008).

Risk factors

The main factors affecting the risk of epithelial cancers of the ovary are reproductive history and contraceptive use, although a small proportion of women are at greatly increased risk due to inherited genetic susceptibility. Overall, the main risk factor appears to be the lifetime number of ovulatory cycles.

One of the first observations linking reproductive history to ovarian cancer risk was that never-married women were at approximately one and a half times the risk of ever-married women. Subsequently, decreasing risk with increasing numbers of full-term pregnancies has been shown in over a dozen case-control studies (Whittemore et al 1992). Typically, having had one or two children is associated with a decrease in risk of approximately 30%, and having had three or more children is associated with a decrease in risk of approximately 60%. In a recent US study of 563 cases and

Figure 34.3 Age-specific mortality rates for ovarian cancer, UK 1971–2007.

523 controls, one child was associated with a 40% reduction in risk, two children with a 60% reduction in risk and five or more children with a 80% reduction in risk (Titus-Ernstoff et al 2001). A large cohort study in Sweden including 4128 ovarian cancer cases found that having had one child was associated with a 25% reduction in risk and having had two children was associated with a 43% reduction in risk (Granstrom et al 2008). The effect of parity does not appear to be attributable to confounding by age at first birth, age at last birth, age at menarche or age at menopause, none of which seem to be associated with ovarian cancer risk to any significant extent.

Infertility, however, does have an independent effect on ovarian cancer risk. In a pooled analysis of eight case-control studies (Ness et al 2002), nulliparous women who tried to conceive for more than 5 years had a 2.7-fold risk of ovarian cancer compared with women who had not tried to conceive for more than 1 year. There have been claims that women who received fertility treatment had an increased risk compared with those who had never been treated with fertility drugs, but there is no evidence to support this claim (Kashyap et al 2004).

Although not established conclusively, breast feeding seems to reduce the risk of ovarian cancer, even after adjusting for parity. A recent prospective study found that women who had breast fed for 18 months or more were at significantly lower risk of ovarian cancer compared with women who had not breast fed (Danforth et al 2007).

Exogenous hormones

The protective effect of the COCP on ovarian cancer risk has been demonstrated beyond any reasonable doubt (Collaborative Group on Epidemiological Studies of Ovarian Cancer 2008). Pooled estimates of the protection indicate that the risk is reduced by approximately 50% with 5 years of use, and that protection increases with the duration of use (Whittemore et al 1992). The protective effect of oral contraceptives persists for up to 30 years after cessation of use, and is not confined to any particular formulation of the pill. The benefit in absolute terms can be expected to increase over the next few decades as the cohort of women with extensive use of oral contraceptives reaches the peak age of ovarian cancer incidence. Hormone replacement therapy has been associated with a 19–24% increased risk of ovarian cancer; however, the risk is not increased in women using

hormone replacement therapy for less than 5 years, and decreases once a woman stops taking it (Zhou et al 2008).

Family history

It is a well-known clinical observation that ovarian cancer tends to aggregate in families. Rarely, such clustering can be extreme with increased risk of breast cancer (in *BRCA1* and *BRCA2* gene mutation carriers) and colon and endometrial cancer in cancer family syndromes. The risk of ovarian cancer associated with *BRCA1* and *BRCA2* mutation carriers is 40% and 18%, respectively (Chen and Parmigiani 2007). Case-control studies generally find a relative risk of approximately 3 associated with one affected family member, and a relative risk of approximately 7 with two affected relatives. More recently, the Swedish Cancer Family Database reported relative risks of 2.54 in women with an affected mother and 2.76 in women with an affected sister (Granstrom et al 2008). Relative risks of such magnitude are typical of most cancers, but the high absolute risk in women with a family history of both early breast cancer and ovarian cancer is such that many such women consider having a prophylactic oophorectomy once they have completed their families, particularly since having an oophorectomy before the natural menopause also reduces the risk of breast cancer.

Other factors

Inconsistent results have been found from epidemiological studies regarding BMI (Vaino and Bianchini 2002). A recent meta-analysis (Schouten et al 2008) concluded that a BMI of 30 or more in premenopausal women increases the risk of ovarian cancer by 30% compared with women with a BMI below 24. No effect was observed in postmenopausal women.

There has been great interest in whether talcum powder applied to the perineal area increases the risk of ovarian cancer. In an attempt to clarify the evidence, a systematic review was carried out in 2003. This found a significantly increased risk associated with talc use (relative risk 1.33, 95% confidence interval 1.16–1.45). However, there was no clear association with dose, and the authors concluded that the association could be confounded or biased (Huncharek et al 2003). A further two case-control studies (Gates et al 2008, Merritt et al 2008) have been published, both of which seem to suggest a significant trend of increasing risk with more frequent use. Despite this finding, the authors advise caution because the majority of studies failed to observe a dose-response relationship and there is the possibility of recall bias differentially affecting cases and controls.

The relationship between smoking and ovarian cancer is unclear. A meta-analysis including 10 studies found that the risk of mucinous ovarian cancer was doubled in current smokers compared with never-smokers; however, a risk reduction for clear cell cancers was also observed (Jordan et al 2006). In 2008, the Norwegian-Swedish Women's Lifestyle and Health cohort including 103,081 women found a doubling of risk for borderline tumours for former and current smokers compared with non-smokers. They also found a dose-response relationship according to smoking intensity and duration for borderline and serous tumours (Gram et al 2008).

Prevention and screening

No effective screening methods are available for the detection of early ovarian cancer. Recent hopes are centred on multimodal screening involving serum tumour marker CA125 for primary screening followed by ultrasound (Menon et al 2009). Transvaginal ultrasound examination on its own is not justified as a screening technique at population level due to its lack of specificity and predictive value, because it is unable to differentiate benign cysts from malignant disease. The serum tumour marker CA125 is present in approximately 80% of epithelial cancers, but is also raised in the presence of other cancers (i.e. pancreatic, breast, bladder) as well as in some benign diseases (e.g. diverticulitis, endometriosis) and some physiological conditions (e.g. pregnancy, menstruation) (Menon 2004). The best evidence to date regarding multimodal screening comes from a large randomized-controlled trial in the UK; although this trial did not find a difference in deaths from ovarian cancer, it did find a significant difference in the median rate of survival in the screened group compared with the control group (Jacobs et al 1999). Currently, the UK Collaborative Trial of Ovarian Cancer Screening has randomized over 200,000 women to multimodal screening or no screening. The main endpoint is death from ovarian cancer, and the results are expected in 2015. In the multimodal arm, triage is offered based on a substantial increase in CA125 and not simply on the absolute level. There is much interest in other proteomic markers detectable in serum, but it is too early to evaluate these fully (Rifai et al 2006, Gagnon and Ye 2008).

Cancers of the Vulva and the Vagina

Cancers of the vulva and vagina account for 7% and less than 2% of all gynaecological cancers in the UK, respectively. Over 80% are squamous in origin, with 10% of vulva cancers being melanomas. Incidence and mortality of both cancers is highest in women over 60 years of age (Figure 34.4). The incidence of vaginal cancer in women over 60 years of age is three per 100,000 in England (compared with less than one per 100,000 in women under 60 years of age). The risk in women over 60 years of age is much more pronounced for vulval cancer; incidence increases from approximately three per 100,000 in women aged 40–59 years to 11 per 100,000 in women aged over 60 years. The incidence of vaginal cancer in the UK has remained at approximately 0.6 per 100,000 for the past 15 years. The incidence of vulval cancer fell during the 1970s and 1980s; however, it has increased in recent years and the incidence rate is now comparable to that observed in 1975 (Figure 34.5). This increase reflects the sharp rise of vulval cases in women under 50 years of age, which in turn is thought to be caused by the high prevalence of HPV infection in younger women (Joura et al 2000). The increase in HPV infection of the vulva has been attributed to changing attitudes towards oral sex. Mortality rates from both cancers have fallen considerably since the 1970s. For vaginal cancer, the rates have fallen by 38% since the 1970s (from 0.4 per 100,000 to 0.2 per 100,000), and for vulva cancer, the corresponding figure is 53% (from 1.3 per 100,000 in 1971 to 0.6 per 100,000 in 2006).

Figure 34.4 Incidence and mortality rates for (A) vulval and (B) vaginal cancer, England 2006.

Figure 34.5 Age-standardized (European) incidence and mortality rates for (A) vulval and (B) vaginal cancers, Great Britain 1971–2006.

Rates of vaginal cancer vary around the world, with the lowest rates observed in Eastern and Western Asia (approximately 0.2 per 100,000) and the highest rates seen in the Caribbean and Southern Asia (0.7 per 100,000). Vulval cancer is much more common in North America and Europe (1.6 per 100,000), and relatively rare in Eastern Asia and Northern Africa (0.3 per 100,000). The geographical distribution for vaginal cancer most probably reflects not only HPV prevalence but the extent of cervical screening available in different populations, as many vaginal lesions are identified at the time of screening for cervical cancer.

Risk factors for these cancers appear to be similar to those for cervical cancer. A well-defined precancerous stage has been identified for both these cancers: vaginal intraepithelial neoplasia and vulval intraepithelial neoplasia. It is estimated that 65–90% of vaginal cancers and 30–35% of vulval cancers can be attributed to HPV infection [WHO/ICO Infor-

mation Centre on Human Papilloma Virus (HPV) and Cervical Cancer 2007]. HPV 16 has been found to be the most prevalent HPV type in both these cancers; it comprised approximately 60% of the HPV found in vaginal cancer (Hampl et al 2006) and 20–60% of the HPV found in vulval cancer. HPV-positive vulvar cancer is much more common in women under 50 years of age, where high-risk HPV types can be detected in up to 60% of cancers (Hampl et al 2008). It has been hypothesized that vulval cancer arises from two distinct diseases (Trimble et al 1996, Basta et al 1999). The first type develops from in-situ vulval neoplasia, in which a much higher proportion of high-risk HPV types are found (70–90%) (Madeleine et al 1997) and which is more prevalent in young women. The second type, which more often afflicts older women, develops from non-cancerous vulvar epithelial disorders as a result of chronic inflammation (the itch-scratch-lichen sclerosis hypothesis) (Canavan and Cohen 2002). Antibodies to herpes simplex virus type 2 have

been associated with increased risk of both vaginal and vulval cancer, even after controlling for HPV infection (Hildesheim et al 1997, Madeleine et al 1997). Smoking increases the risk of vulval cancer six-fold, and this increases to 25-fold when heavy smoking (>20 cigarettes a day) and HPV infection interact (Hildesheim et al 1997, Madeleine et al 1997). The association between smoking and vaginal cancer still remains uncertain.

The one risk factor that is very strongly associated with cancer of the vulva is immunosuppression; the risk of invasive vulval cancer is increased 100-fold in women with renal transplants (Penn 1986). It has also been documented that

the incidence of vulval intraepithelial neoplasia is increased in women who are HIV positive (Frisch et al 2000).

Vaginal cancer in adolescents has been attributed to in-utero exposure to diethylstilbestrol (DES), a synthetic oestrogen used to prevent spontaneous abortions between 1940 and 1970 (Greenwald et al 1971). Vaginal cancer is almost never diagnosed in cohorts who could not have been exposed to DES *in utero* (either because they were born prior to 1945 or because DES was never prescribed in the country). The current estimates suggest a 40-fold increase in the risk of vaginal cancer in the daughters of exposed women (Hatch et al 1998).

KEY POINTS

1. Breast cancer and cervical cancer are the two most common female malignancies in the world.
2. Cervical cancer is most common in developing countries while uterine corpus and ovarian cancer have a higher incidence in industrialized countries.
3. The variation in the rates of gynaecological cancers around the world is enormous.
4. Well-organized cytological screening has had a dramatic effect on the incidence and mortality rates of cervical cancer.
5. HPV infection is very common, but only a tiny minority of women infected with HPV develop cervical cancer. The development of cancer depends on the persistence of HPV infection.
6. HPV testing offers the potential for improving the effectiveness and feasibility of cervical screening, particularly in the developing world.
7. In the long term, vaccination against HPV may eliminate cervical cancer completely.
8. The incidence of endometrial cancer in women over 55 years of age has been increasing in the UK, while rates in premenopausal women have been decreasing.
9. Obesity and oestrogens are the main factors associated with endometrial cancer.
10. The oral contraceptive pill has reduced the incidence of ovarian cancer in women aged 30–44 years. The rise in incidence in older women has been attributed to increased prevalence of obesity.
11. Incidence of ovarian cancer is only slightly greater than the mortality rates, reflecting the poor cure rate.
12. Reproductive history and contraceptive use are the main risk factors for ovarian cancer.
13. Detecting ovarian cancer at an early stage is key to increasing survival. A large randomized controlled trial is ongoing assessing the effectiveness of serum tumour marker CA125 followed by ultrasound examination as a screening tool.
14. A large proportion of vaginal and vulval cancers are attributed to HPV infection.

MANAGEMENT OF FAMILIAL GYNAECOLOGICAL CANCER	528		

Introduction

Enormous progress has been made in understanding the molecular basis of disease during the last decade, and this has transformed our understanding of the process of carcinogenesis. In recent years, these developments have started to have an impact in gynaecological cancer. Although the details of molecular research and technology are frequently complex and often of limited relevance to clinicians, the underlying principles provide a coherent and comprehensible framework of the process of carcinogenesis. The fundamental understanding of the process of carcinogenesis achieved using molecular technology provides exciting opportunities for the prevention, early detection and treatment of cancer. Molecular knowledge has not yet had a major impact in clinical oncology, but the potential impact is clear and is likely to emerge during the next decade.

During the past century, human cancers have been categorized by their microscopic appearance (histology), and each category has been linked to a certain clinical behaviour and prognostic significance. However, cancer patients with similar histological tumour types and stage of disease may have a different clinical outcome. It has become clear that biological diversity of tumours cannot be explained by microscopic appearance alone. The current focus of profiling tumours is the large-scale analysis of gene expression using new DNA microarray technology. By surveying thousands of genes at once, it is now possible to read the molecular signature of an individual patient's tumour. Analysing these complex data sets might introduce new tumour classes. The ultimate goal is to move beyond standard tumour classification to achieve more detailed insight into the biological aggressiveness of tumours, and to develop more specific potential therapeutic targets (e.g. gene therapy). It will,

therefore, become increasingly important for clinicians involved in the management of gynaecological malignancies to have a working knowledge of the molecular basis of carcinogenesis.

Gynaecological cancers provide examples of a number of contrasting mechanisms of carcinogenesis (Figure 35.1). For example, ovarian and endometrial cancer can occur as components of familial cancer syndromes (familial breast/ovarian cancer and Lynch II syndrome) due to germline inheritance of predisposing genetic abnormalities. However, most ovarian cancers are not thought to be due to inherited genetic alterations, but result from somatic mutations occurring in ovarian cells with an initially normal genome. These somatic mutations are thought to be secondary to environmental factors that act to increase the opportunity for spontaneous mutation in a number of critical genes. One of the genetic alterations that lead to cervical cancer is caused by an environmental factor, human papilloma virus (HPV), and in at least some endometrial cancers, unopposed oestrogen exposure or hyperinsulinism leads to carcinogenesis. High-risk subtypes of HPV are much less common in vulval cancer. This suggests that vulval and cervical carcinomas are not identical aetiologically, and that factors other than HPV are more important in vulval carcinogenesis. There is recent evidence that different genetic events occur between HPV-positive and -negative vulval cancers, with a greater number of molecular alterations in HPV-negative vulval cancers compared with HPV-positive tumours (Flowers et al 1999). HPV-positive vulval cancers are more frequently found in younger patients. Vulval cancers in older patients are more often HPV negative, and more frequently show allelic loss of the *TP53* gene.

The histological features, and biological and clinical behaviour of fallopian tube cancers are similar to those of

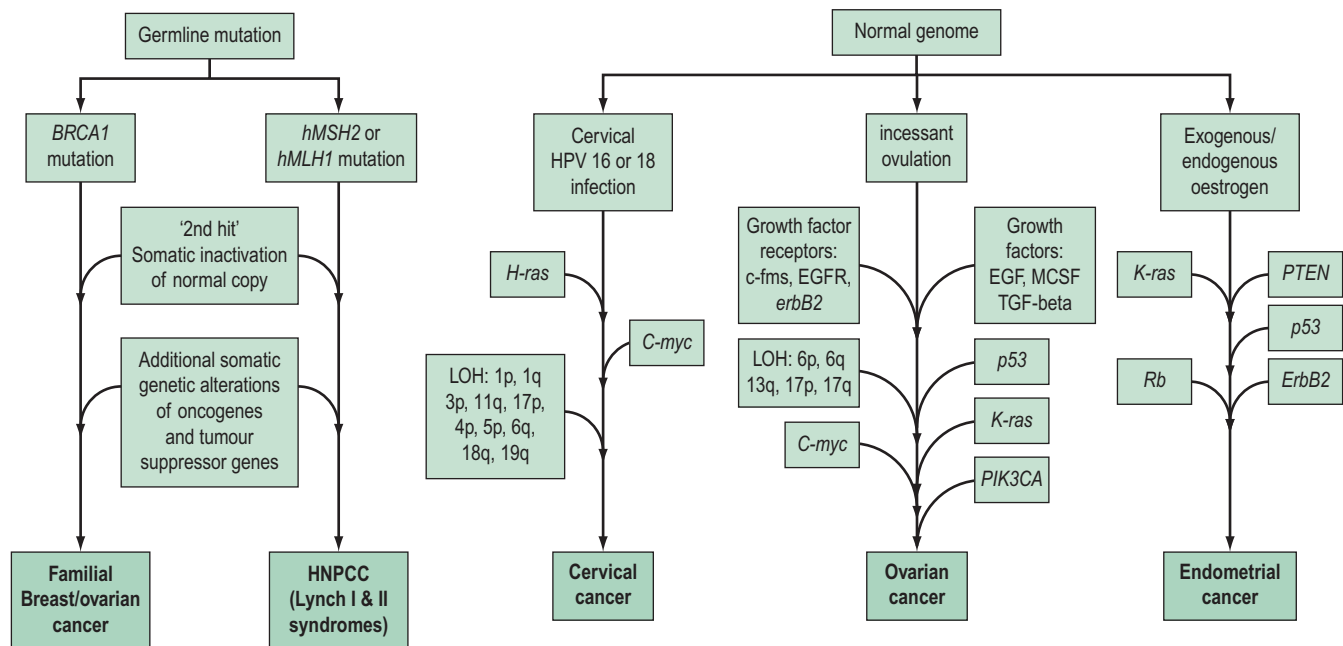

Figure 35.1 Pathways of carcinogenesis in familial and sporadic gynaecological cancer.

ovarian cancer. In addition, there is evidence that similar genetic alterations occur with the same frequency in fallopian tube and ovarian cancers of the same histological subtype. This suggests a common molecular pathogenesis between these cancer types (Levanon et al 2008).

To date, little is known about the molecular genetics of vaginal cancer.

Molecular Basis of Carcinogenesis

A fundamental characteristic of cancer cells is loss of the normal restraints controlling cell division, cell-to-cell interaction and cellular mobility. The fact that this characteristic is passed on to cells arising from the division of cancer cells has long been regarded as evidence for a genetic basis for carcinogenesis, and is supported by a number of other observations. First, agents which cause damage to DNA (chemical mutagens, ionizing radiation and some viruses) also increase susceptibility to cancer. Second, studies of the clonal origin of tumours indicate that the vast majority of cancers arise from a single cell which passes on its abnormality to daughter cells. An initial genetic alteration provides a selective advantage for proliferation of a clone of cells, and further genetic alterations within this expanded population of cells increase the selective proliferative advantage and eventually lead to the formation of a clinically recognizable tumour.

During the last decade, it has become clear that the genetic changes in cancer involve genes which control normal cell growth and proliferation. Cells communicate via a complex interacting set of signalling pathways, the principles of which, unlike the details, are well established (Figure 35.2). The best understood mechanism of communication between cells is via the release of molecules which interact as agonists with receptors either within the cell or, more frequently, in

the cell membrane. This interaction results in a further signal within the cell which, via transducer proteins and secondary mechanisms, results in modified cell behaviour either by activating already synthesized target enzymes directly or by initiating transcription of genes and synthesis of their protein product. The genetic abnormalities observed in cancer are known to affect genes coding for all of the groups of molecules in Figure 35.2.

Oncogenes

The identification of oncogenes resulted from in-vitro and animal work with virus-induced cancers. As the viral genome is relatively small, it was possible to identify the specific genes (viral oncogenes) involved in the transforming activity of retroviruses, such as the Rous sarcoma virus. It was possible to identify homologous genes in normal cells, and a number of viral oncogenes were found to have normal cellular homologues known as 'proto-oncogenes'. Other workers identified oncogenes by transfecting cell lines with DNA from human cancer cell lines, and found that some of the transforming oncogenes identified were mutated versions of the proto-oncogene identified by the retroviral approach. Subsequently, it was demonstrated that chromosome translocations such as the Philadelphia chromosome in chronic myeloid leukaemia involved known oncogenes (de Klein et al 1982).

Approximately 100 proto-oncogenes have been identified, and many can be assigned to the groups of functions summarized in Figure 35.2. The mutation resulting in conversion of a proto-oncogene into an oncogene may occur in several different ways (Figure 35.3), and may result in an abnormal protein produced in a normal quantity, a normal protein produced in an excessive amount, or a normal protein produced inappropriately due to loss or alteration of control regions of the gene.

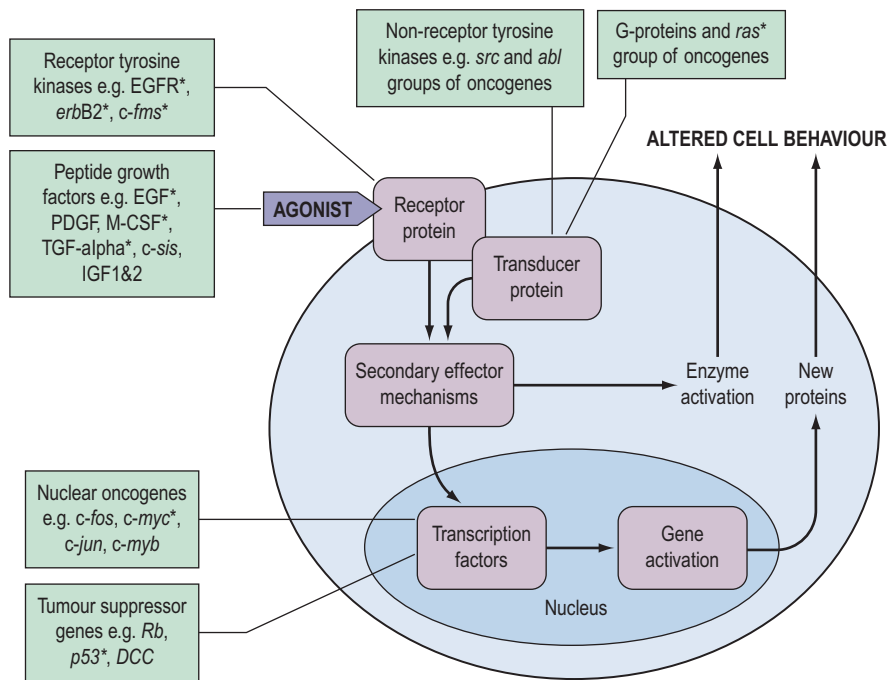

Figure 35.2 An overview of the role of oncogenes and tumour suppressor genes in the control of cell growth and proliferation. The purpose of this figure is to emphasize that the genetic abnormalities in cancer are a result of alterations to or abnormal expression of genes which are normally involved in cell regulation. Genes which are implicated in ovarian carcinogenesis are marked with an asterisk. Note that many aspects of the figure are oversimplified for clarity; for example, although a function of *p53* and *Rb* is transcriptional regulation, this is not true of all tumour suppressor genes.

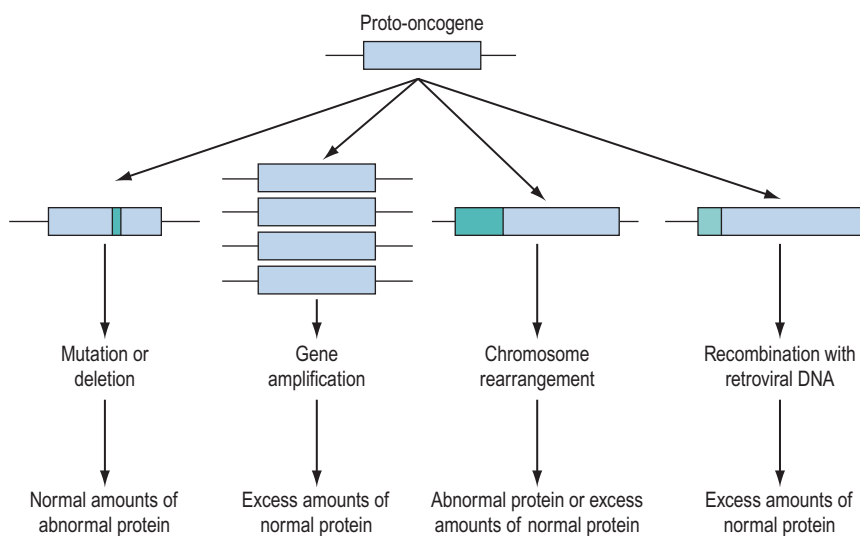

Figure 35.3 A summary of the mechanisms of activation of oncogenes.

Tumour suppressor genes

The existence of tumour suppressor genes was suggested by cell fusion studies of transformed cells and non-transformed cells which resulted in a non-transformed hybrid cell. The subsequent identification of the first tumour suppressor gene followed from the study of retinoblastoma, a rare childhood cancer which may occur in a hereditary and sporadic form. On the basis of epidemiological and statistical analysis, Knudson suggested that development of the cancer required two events. He postulated that in the hereditary form, the first event was a germline mutation present in every cell of the individual, and that a second event in any of the many million retinoblasts could result in tumour formation. The rarity, later onset and unilateral nature of the sporadic form could be attributed to the need for two events in a single

retinal cell in the absence of a germline mutation. When the retinoblastoma (*Rb*) gene was mapped to chromosome 13q and cloned, it was confirmed that in both familial and sporadic retinoblastoma, the two copies of the gene were inactivated in tumour cells, consistent with Knudson's 'two-hit' hypothesis (Cavenee et al 1983).

Knudson's hypothesis that two hits are required for the full inactivation of a tumour suppressor gene has been shown to be fundamentally correct in almost all cases of human cancer. However, the fact that methylation of CpG islands located in the promoters of genes can cause transcriptional silencing, coupled with the observation that DNA methylation patterns are perturbed in cancer cells, has led to the suggestion that abnormal methylation of the promoters of tumour suppressor genes might be implicated in carcinogenesis, and can serve as a third pathway to inactivation of

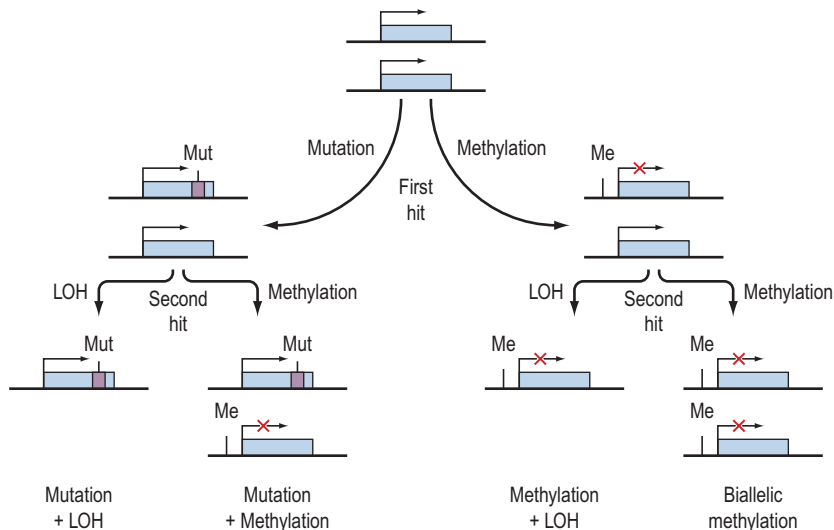

Figure 35.4 Besides loss of heterozygosity (LOH) and mutations (mut), DNA methylation (Me) is the third possibility to inactivate a tumour suppressor gene. Source: From *Nature Genetics*, Laird and Jones; *Cancer-epigenetics comes of age*; 21: 163–7; 1999.

Figure 35.5 DNA methylation and regulation of gene activity. Genes without methylation at their 5' region can be transcribed into RNA and translated into protein (e.g. tumour suppressing proteins). De-novo DNA methyltransferases (DNMT3A and 3B) initiate methylation of cytosines which are located in front of a guanine (CpGs), and the maintenance DNA methyltransferase (DNMT1) ensures that once a cytosine is methylated, it will become methylated immediately after cell division. Methylated genes attract proteins which modify the chromatin and therefore suppress the expression of these genes.

a tumour suppressor gene (Figure 35.4) (Jones and Laird 1999).

Epigenetics and DNA methylation in cancer

As outlined above, aberrant gene function and altered patterns of gene expression are key features of cancer. Growing evidence shows that acquired epigenetic abnormalities participate with genetic alterations to cause this dysregulation. The modern definition of epigenetics is modifications of the DNA or associated proteins, other than DNA sequence variation, that carry information content during cell division. The best understood example of epigenetic modification is DNA methylation, a covalent addition of a methyl group derived from S-adenosyl-L-methionine to the fifth

carbon of the cytosine ring to form the fifth base, 5-methylcytosine (5meC) (Laird 2003, Jones and Baylin 2007). The reaction is catalysed by DNA methyltransferases together with accessory proteins. Among all eukaryotic species, methylation occurs predominantly in cytosines located 5' of guanines, and known as 'CpG dinucleotides' (CpGs). In the mammalian genome, the distribution of CpGs is far from random. CpGs are greatly under-represented in the genome through evolutionary loss of 5meC through deamination to thymine. However, clusters of CpGs known as 'CpG islands' (CGIs) are present in 1–2% of the genome. Typically, they range in length from 200 to 5000 base pairs (bp). Most are unmethylated under normal circumstances, with the exception of those associated with imprinted genes, genes subjected to X-chromosome inac-

tivation and transposable elements. In this last respect, DNA methylation is thought to repress faulty expression of endogenous transposons that may disrupt the genome. It is also involved in the parental-specific silencing of one allele of imprinted genes. In addition, approximately 70% of CGIs are associated with DNA sequences 200–2000 bp long found in the promoter, the first and second exons, and the first intron regions of all genes (5' CGIs). This suggests that CGIs are critical in gene regulation. There is, for instance, usually an inverse relationship between the degree of methylation of a regulatory CGI and the extent of gene transcription (Figure 35.5) (Laird 2003, Jones and Baylin 2007).

DNA methylation patterns are established during defined phases in embryonic development. With the exception of imprinted genes, gamete methylation patterns are erased by a genome-wide demethylation at around the eight-cell stage of blastocyst formation. During the implantation stage, methylation patterns are re-established via de-novo methylation. During adulthood, the degree and patterns of methylation are both tissue- and cell-type specific. Disruption of these preset patterns of DNA methylation in adult life has been linked to ageing and to disease. Furthermore, dysregulation of developmental programming by maternal factors or environmental mimics is thought to induce abnormal DNA methylation of specific genes and hence their faulty expression, leading to disease (Laird 2003, Jones and Baylin 2007).

Over the last decade, the importance of epigenetic gene regulation has become increasingly evident as studies have shown that each epithelial tumour only contains approximately 10–15 tumour suppressor genes silenced through mutations, but several hundred silenced through DNA methylation (Jones and Baylin 2007, Thomas et al 2007). Numerous genes involved in central pathways can be silenced by means of DNA methylation (Figure 35.3).

Germline and somatic genetic alterations

A common feature of tumours is that they accumulate somatic genetic changes during the development of the cancer. A proportion of cancers may also develop as a result of germline mutations in cancer predisposing genes. An important distinction must be made between germline and somatic mutations. Somatic mutations are found in the tumour cells but not the normal cells of an individual with cancer, and cannot therefore be passed on to descendants through the germline. Germline mutations, however, are present in all the cells of the individual and can initiate tumour development. They can be passed on to descendants of the individual, and can be identified in DNA obtained from all diploid cell populations (e.g. peripheral blood samples) and not just the tissues that are susceptible to disease. It is worth pointing out that the same genes mutated in the germline are also frequently mutated in the somatic cells of a cancer, which suggests a functional significance for specific genes in cancer development. For example, mutations of the *p53* gene are one of the most common genetic changes found in human cancer. In most cancers, *p53* mutations occur as somatic events, but germline *p53* mutations are often found in patients from families with the rare Li-Fraumeni syndrome, which is characterized by sarcomas, breast cancer and other malignancies occurring at a young

age. Another example is the colorectal cancer predisposition syndrome, familial adenomatous polyposis (FAP), caused by germline mutations in the *APC* gene (Kinzler et al 1991). The FAP syndrome is responsible for approximately 1% of all colorectal cancers, but somatic mutations of *APC* have been detected in over 80% of sporadic colorectal cancers and appear to be one of the earliest events in colorectal carcinogenesis.

Most of the familial cancer syndromes identified to date are rare, single gene disorders and have an autosomal-dominant pattern of inheritance. Individuals inheriting the germline abnormality are generally at high risk of developing malignancy because the penetrance of most of these genes is of the order of 80%. Another class of cancer predisposition genes that confer more modest penetrance has been identified recently. Although these genes are associated with much lower penetrance, they are also much more common in the population than the rare high-risk genes, and so are probably responsible for a greater proportion of cancer overall (reviewed in Easton and Eeles 2008). However, the identification of individuals in the population that are likely to carry these low penetrance genes is not easy because they are not often associated with a significant family history of disease.

Genetics of Familial Gynaecological Cancer

Although there are anecdotal reports of more than one case of vulval cancer occurring in close relatives, there is no good evidence of inherited predisposition to this disease. For cervical cancer, the absence of any obvious clustering of multiple cases within families suggests that no highly penetrant susceptibility loci for the disease await identification. However, population-based epidemiological studies suggest that shared genetic factors do play a role in the development of cervical cancer, and possibly account for approximately 27% of cases. This perhaps suggests the presence of several common genetic variants that confer low penetrance disease risk. Ovarian and endometrial cancers occur as part of well-defined cancer family syndromes with an autosomal-dominant inheritance pattern. Pedigree studies of cancer within families have revealed three main syndromes associated with ovarian cancer. The most common hereditary form of ovarian cancer occurs in association with breast cancer. A large number of hereditary breast/ovarian cancer families have been described in which there is a high frequency of both cancers and an association with an early age of onset. Hereditary ovarian cancer may also occur as a site-specific disease, although genetic studies suggest that a large proportion of site-specific ovarian and breast/ovarian cancer families are part of the same disease spectrum. Nevertheless, there remains evidence that there is a rare genetic component that confers high penetrance susceptibility specifically to ovarian cancer (reviewed in Ramus and Gayther 2009). Less frequently, ovarian cancer occurs in hereditary non-polyposis colorectal cancer (HNPCC) families, and germline genetic mutations in highly penetrant genes that cause HNPCC have been found in ovarian cancer cases from these families. Women from HNPCC families most frequently develop colorectal or endometrial cancer, and this is the syndrome most commonly associated with genetic predisposition to endometrial

cancer. Some families have recently been described with an apparently high risk of site-specific endometrial cancer. It is important to recognize that when all of these familial syndromes are combined, they are probably responsible for less than 5% of ovarian cancer cases and a smaller proportion of endometrial cancer cases.

The *BRCA1* and *BRCA2* genes

The identification and detailed pedigree-based descriptions of families at high risk of breast and ovarian cancer, together with the development of polymorphic DNA markers, made it possible to perform detailed linkage analysis with the aim of locating genes involved in familial cancer. A major step forward was the report of linkage of early-onset breast cancer to the polymorphic marker CMM86 located on chromosome 17q (Hall et al 1990). Subsequently, linkage to 17q in 214 families was confirmed by a consortium of 13 research groups from Europe and the USA (Easton et al 1993). Almost all breast/ovarian cancer families and 40% of families with breast cancer alone were found to have a linkage with the *BRCA1* (Breast Cancer 1) locus on chromosome 17q. Subsequently, the consortium localized the gene to a 2cM region on 17q, and in 1994, a group in Utah described a large gene on 17q within which they had identified mutations in five affected families (Miki et al 1994). Subsequent work by other research groups has confirmed that this gene is the *BRCA1* gene, and over 12,000 carriers of a *BRCA1* mutation have now been described in breast/ovarian cancer families and cancer cases unselected for a family history [described on the Breast Cancer Information Core (BIC) database: <http://research.nhgri.nih.gov/bic/>].

BRCA1 is a large gene with 22 exons encoding a protein of 1863 amino acids. There are no specific hotspots for mutation in the gene, and only a small proportion of mutations are recurrent. Overall, the penetrance of a *BRCA1* mutation for ovarian cancer and breast cancer appears to be 40–50% and 80%, respectively (Ford et al 1994, 1998). However, there is evidence that penetrance may be modified by both environmental factors and other genetic influences. Furthermore, the location of a mutation within the *BRCA1* gene may influence both the overall risk of cancer and the type of cancer. Gayther et al (1995) reported a correlation between mutations toward the 3' end of the gene and a greater risk of ovarian cancer than breast cancer. Well-defined founder mutations have been described in *BRCA1*. Mutations at 185delAG and 5382insC have been documented in approximately 1% of Ashkenazi Jewish cancers, and up to 40% of Ashkenazi Jewish women with ovarian cancer or early-onset breast cancer. Identification of *BRCA2* closely followed the cloning of *BRCA1*. Wooster et al (1995) identified the gene following studies involving high-risk families in which the disease pattern was not linked to *BRCA1*.

BRCA2, located on chromosome 13q, is also a large gene with 26 coding exons encoding a protein with 3418 amino acids. More than 11,000 mutation carriers have been described to date (the BIC database). As for *BRCA1*, there are no hotspots for mutation, although there are founder mutations in some ethnic groups such as Ashkenazi Jews (Levy-Lahad et al 1997, Thorlacius et al 1997). Although the penetrance for breast cancer is approximately 80%, the penetrance for ovarian cancer seems to be lower than that for *BRCA1* mutations at approximately 25% (Ford et al 1998).

There is a suggestion that mutations in exon 11 confer a higher risk of ovarian cancer than mutations in other areas (Gayther et al 1997). This has been confirmed in a more recent meta-analysis (reviewed in Ramus and Gayther 2009). Overall, *BRCA1* and *BRCA2* are believed to account for over 95% of hereditary cases of ovarian cancer and over 80% of hereditary cases of breast cancers.

The functions of *BRCA1* and *BRCA2* are still unclear. Most of the mutations of *BRCA1* are small insertions or deletions, which result in loss of protein synthesis or production of a truncated protein. This observation supports the concept that *BRCA1* functions as a tumour suppressor gene. In this 'two-hit' model, although one copy of the gene is inherited as an inactive mutant form, the development of cancer requires somatic mutation of the other wild-type ('normal') gene copy. Analysis of tumours from familial breast/ovarian cancer families has demonstrated that loss of heterozygosity (LOH) in these tumours involves the wild-type gene, thus providing further evidence that the *BRCA1* gene is a tumour suppressor (Smith et al 1992). Both *BRCA1* and *BRCA2* are expressed in the largest amounts in the testis and thymus, and at lower levels in the breast and ovary. Although the genes have limited sequence homology, they do have similarities including being A-T rich, having a large exon 11 with the start of translation at codon 2. The presence of a zinc finger motif in *BRCA1* has suggested a role as a transcription factor, whilst *BRCA2* has homology with known transcription factors. However, the most compelling functional evidence indicates that *BRCA1* and *BRCA2* both play a major role in homologous and non-homologous DNA double-strand break (DSB) repair through their interaction with the RAD51 DSB protein. It is still not known why abrogation of such a ubiquitous cellular function should predispose individuals specifically to breast and ovarian cancer.

HNPCC-associated gynaecological cancer and DNA repair genes

HNPCC is associated with autosomal-dominant inheritance of colorectal cancer in those who do not have the multiple adenomas which occur in FAP. The identification of the genetic basis of Lynch II syndrome is a notable example of the power of molecular technology. HNPCC was classified by Henry Lynch into site-specific hereditary colon cancer (Lynch I syndrome), and families with a predisposition to non-polyposis colorectal cancer in association with other cancers including stomach, small bowel, ureter, renal pelvis and brain, as well as ovarian and endometrial cancer (Lynch II syndrome) (Lynch 1985). The identification of the genes responsible for HNPCC was a result of several developments which showed that HNPCC is associated with hereditary defects in one of five DNA mismatch repair genes [mutS homolog 2 (*MSH2*), mutL homolog 1 (*MLH1*), postmeiotic segregation increased 1 (*PMS1*), postmeiotic segregation increased 2 (*PMS2*) and mutS homolog 6/G/T mismatch-binding protein (*MSH6/GTBP*)]. Hundreds of mutations have been identified in these five genes in HNPCC families, making mutation testing a difficult challenge in these families (Lynch and de la Chapelle 1999). Available evidence suggests that these genes function as tumour suppressor genes in a manner consistent with Knudson's 'two-hit' model. The inherited germline mutation inactivates one

copy of the mismatch repair gene, but inactivation of the remaining wild-type copy by a second somatic mutation is required prior to tumour formation. The secondary, acquired mutations which result from loss of DNA repair gene function include defects of *APC*, *K-ras*, *DPC4* and *p53* (Huang et al 1996, Kinzler and Vogelstein 1996). The penetrance for colorectal cancer in mutation carriers is in excess of 80% in men and 30% in women, and HNPCC accounts for approximately 5% of colorectal cancers (Dunlop et al 1997, Aarnio et al 1999, Salovaara et al 2000). Endometrial cancer is the second most common cancer in HNPCC families, with female carriers having a 42% risk by 70 years of age (Dunlop et al 1997). The penetrance for ovarian cancer is less, with a reported lifetime risk of 9% (Marra and Roland 1995).

Management of Familial Gynaecological Cancer

Risk assessment

At present, risk assessment is based largely upon information derived from a detailed family tree. Important information includes the number of cases of cancer relative to the number of people at risk, the pattern of cancers of different types, and the age at diagnosis of cancer. For a number of reasons, risk assessment should ideally be undertaken in the setting of a multidisciplinary specialist familial cancer clinic run by a geneticist working with a team of genetic counsellors and with close links to specialists in areas such as gynaecological, colorectal and breast cancer. Obtaining a detailed family history and confirming the history with clinical and histopathological information is time consuming and requires an organization and resources specifically established for this purpose. The interpretation of family histories is not always straightforward, particularly when there are a variety of different primary sites in the family. Specialist training is required to counsel patients about the implications and consequences of genetic testing. Particular expertise is also required to provide the patient with sound advice about methods of prevention and screening.

Although it is difficult to precisely define the minimum family history necessary to satisfy the description of a familial cancer syndrome involving a gynaecological cancer, some broad guidelines can be outlined:

- families in which two first-degree relatives have ovarian cancer;
- families in which first-degree relatives have breast cancer at less than 50 years of age and ovarian cancer; and
- families in which two first-degree relatives have breast cancer at less than 60 years of age and a third relative has ovarian cancer.

The likelihood that the high frequency of cancer in such families is due to an inherited predisposition rather than a chance event is in excess of 60%. Families in which one relative has ovarian or endometrial cancer and two or more first-degree relatives have cancer of the colon/rectum, at least one at less than 50 years of age, can be classified as HNPCC families. Although the *BRCA1* gene and DNA repair genes have now been identified, there are still limitations in the

analysis of these genes for mutations in the clinical setting. The genes are large and the mutations are not localized to specific regions of the gene. Nevertheless, the availability and speed of techniques for the detection of mutations is improving rapidly. Mutation testing is now widely available for high-risk families via clinical genetics centres in the UK after thorough counselling about the implications of testing.

Prevention of familial cancer

Use of the oral contraceptive pill may be suggested for HNPCC and breast/ovarian cancer family members on the basis of case-control studies in the general population which indicate a protective effect against ovarian and endometrial cancer. While one study has suggested a protective effect of the oral contraceptive pill in *BRCA1* and *BRCA2* carriers, this was not confirmed in a second study and the situation remains unclear (Modan et al 2001). Furthermore, there is concern in breast/ovarian cancer families that a reduction in risk of ovarian cancer may be offset by an increased risk of breast cancer.

Prophylactic salpingo-oophorectomy and hysterectomy as a primary procedure is justifiable in women from breast/ovarian cancer and HNPCC families after completion of their family and after thorough counselling. There is convincing evidence that salpingo-oophorectomy is an effective method of prevention of cancer of the ovary, fallopian tube and breast. A recent meta-analysis (Rebbeck et al 2009) of all reports of preventative surgery in *BRCA1* and *BRCA2* mutation carriers from 1999 to 2007 revealed a reduction in risk of breast cancer (hazard ratio 0.49) and ovarian/fallopian tube cancer (hazard ratio 0.21). Women undergoing prophylactic surgery should be counselled that the procedure will prevent ovarian and tubal cancer, but that they may still be at risk of primary peritoneal cancer.

It should also be noted that cases of intra-abdominal carcinomatosis following oophorectomy have been reported in which subsequent review of the oophorectomy specimen revealed a small focus of ovarian cancer (Chen et al 1985). Surgery should therefore include a careful inspection of the abdomen and pelvis, and thorough histological examination of the ovary. Fallopian tube cancer does seem to be more common in *BRCA1* and *BRCA2* families, so prophylactic surgery should include salpingectomy. Hysterectomy should be advised for women from HNPCC families, but women from breast/ovarian cancer families do not appear to be at increased risk of endometrial cancer and the decision regarding hysterectomy will depend on other factors.

Screening for familial cancer

The efficacy of ovarian cancer screening is unproven to date, although a survival benefit was noted in a pilot randomized trial in the general population (Jacobs et al 1999). The preliminary results of the UK Collaborative Trial of Ovarian Cancer Screening (UKCTOCS), a larger randomized trial involving 202,000 postmenopausal women from the general population, are encouraging (Menon et al 2009) but there will not be definitive data on mortality impact until 2015. Although the value of ovarian cancer screening is therefore unclear, there is a consensus that it is reasonable to screen women from breast/ovarian cancer families with

transvaginal ultrasonography and serum CA125 measurement in view of their level of risk. Screening is usually performed on an annual basis from the mid 30s or 5 years prior to the earliest age of onset of ovarian cancer in the family.

It should be noted that both CA125 and ultrasound are associated with a substantial risk of false-positive results, leading to unnecessary surgery (Campbell et al 1993, Jacobs et al 1993). It is essential to warn women clearly about this risk. The false-positive rate for both CA125 and ultrasonography is approximately 1–2% in postmenopausal women and higher in premenopausal women. It is therefore likely that a 30-year-old woman undergoing annual screening for up to 50 years will have a false-positive result at some stage, with consequent anxiety and the risk of unnecessary surgery.

Women from breast/ovarian cancer families may be advised to commence screening with mammography from the mid 30s or 5 years prior to the earliest age of onset of breast cancer in their family, although the value of mammography in premenopausal women is controversial. Women from HNPCC families should be advised to undergo regular colonoscopy and mammography in addition to ovarian cancer screening. Ultrasound screening for endometrial cancer has a significant false-positive rate and lack of evidence for a mortality benefit, but is often offered to this group of women because of the particularly high risk. Ultrasound measurement of endometrial thickness can be performed at the time of screening for ovarian size and morphology. It is reasonable to add an outpatient form of endometrial sampling, such as pipelle aspiration. These screening strategies are currently recommended on a pragmatic basis in view of the high risk of cancer, rather than on the basis of clear evidence concerning their efficacy.

Women with a family history not consistent with a familial syndrome

Most women who seek advice about a family history of gynaecological cancer have one affected first-degree relative and do not fall into a familial syndrome. Requests for advice from this group of women have increased dramatically following recent media publicity about screening for ovarian cancer and identification of the *BRCA1* and *BRCA2* genes. Although women with a first-degree relative with ovarian cancer are at increased risk compared with the general population, the absolute risk remains small. They should be reassured that although their risk of ovarian cancer may be increased several fold, it remains low (lifetime risk of 4–5% vs 1% in the general population). Screening with either CA125 or ultrasound should not be offered routinely on a population basis to these women for two reasons. First, an improvement in prognosis for ovarian cancer through detection by screening has not been demonstrated. Second, because the incidence of ovarian cancer in this population is relatively low, the risk of a false-positive result resulting in surgical investigation is likely to be more than 10 times that of a true positive result (i.e. the positive predictive value of screening is <10%). The value of screening for women in this group and for those without a family history awaits evaluation in the UKTOCS trial. Oophorectomy should not be recommended as a primary procedure, but may be considered as a secondary procedure at the time of surgery for benign disease (e.g. hysterectomy).

Molecular Genetics of Sporadic Gynaecological Cancer

Cervical cancer

The histopathological progression of cervical neoplasia from mild to increasingly severe dysplasia and ultimately invasive cervical cancer is well described, as is the evidence for an association with HPV infection. HPV infection is a necessary but insufficient cause for cervical cancer. Infection with oncogenic types of HPV is very common, but most of these infections go unnoticed. Carcinogenesis is a very rare outcome of HPV infection and it clearly involves interactions of the host, the environment and the virus. During recent years, important progress has been made in understanding the mechanism of HPV-induced carcinogenesis and incorporating these findings with the principles of multistep carcinogenesis. HPVs form a group of more than 80 viruses, most of which give rise to benign tumours such as wart infections. The risk of cervical neoplasia is associated with particular HPV types (HPV 16 and 18) (zur Hausen 1987). The genomes of all HPVs have a similar organization which encodes eight major open reading frames encoding early (E1–7) and late (L1–2) viral proteins. It is the early proteins E6 and E7 which are responsible for the transforming activity of the virus (Whiteside et al 2008). The E6 and E7 proteins of high-risk HPV types (HPV 16 and 18), but not those of low-risk types, cause in-vitro changes which parallel the changes in cervical intraepithelial neoplasia (Whiteside et al 2008).

During a normal viral infection resulting in production and release of new virus, the viral genome exists episomally (closed circular DNA) without integration in the nucleus of the infected cell. In tumour cells, the viral DNA is integrated with the DNA of the host cell. Although the sites of integration of viral DNA are random in cancer cell lines and many of the viral genes are lost, the E6 and E7 viral open reading frames are always conserved and are the most abundant viral transcripts in such cell lines (Whiteside et al 2008). Furthermore, integration of E6 and E7 usually occurs in a manner which disrupts the normal viral regulation of expression of these proteins. These observations suggest that E6 and E7 have an important role in cervical carcinogenesis, and are supported by evidence that these proteins can interact with and inactivate several important cellular proteins. E7 binds to the product of the *Rb* tumour suppressor gene, interfering with normal protein complex formation and disrupting the normal function of Rb protein. E6 interacts with the protein product of the *p53* tumour suppressor gene, causing rapid breakdown of the protein and loss of normal *p53* function. The overall effect of E6 and E7 expression in the cell is therefore equivalent to loss of the *Rb* and *p53* tumour suppressor genes. This is consistent with the observation that *p53* mutation is uncommon in cervical cancer but is found in HPV-16- and HPV-18-negative cervical cancer cell lines. E6 and E7 also interact with several other important cellular proteins (involved in adhesion, apoptosis, cell cycle, DNA repair, signal transduction and transcription) affecting the integrity of key pathways, as demonstrated in several in-vitro studies (Whiteside et al 2008).

Clinical and experimental evidence suggests that in common with other mechanisms of carcinogenesis, HPV infection alone is not sufficient to cause cervical cancer, but

requires other factors which may influence local immune responses or result in other genetic alterations. First, high-risk genital HPV infection is very common, and the majority of individuals clear their infection with time. However, a proportion of women, approximately 15%, cannot clear the virus effectively, and the persistence of a high-risk HPV is the major risk factor for the development of anogenital malignancies. Immunosuppressed women (e.g. human immunodeficiency virus infection, transplant recipients) have a substantially increased risk of developing cervical cancer. Second, epidemiological studies suggest that other factors such as smoking and herpes simplex infection may play a role. Third, a number of genetic abnormalities have been identified in cervical cancers. These include amplification or overexpression of *c-myc*, mutation of *c-H-ras* and LOH at a number of chromosomal loci. Recurrent LOH is identified in chromosome regions 3p14–22, 4p16, 5p15, 6q21–22, 11q23, 17p, 18q12–22 and 19q13. All these regions may harbour potential tumour suppressor genes. Several studies reported amplification of chromosome 3q24–28 in up to 90% of cervical cancers. Comparative genomic hybridization (CGH) is a powerful molecular tool which allows screening of the entire genome of a tumour for genetic alterations by highlighting regions of altered DNA sequence copy numbers. CGH from preinvasive (dysplastic) cervical cells reveals several chromosomal imbalances. Most frequent gains were found on chromosomes 1p, 2q, 4 and 5, whereas losses could be found on chromosome 13q (Aubele et al 1998). As outlined above, epigenetic alterations regulate gene expression without changing the DNA sequence. As well as methylation of cytosine in DNA, these alterations include acetylation of histone proteins. Epigenetic alterations are increasingly recognized as important oncogenic mechanisms, and HPV-associated oncogenesis is no exception (reviewed in Whiteside et al 2008). DNA methylation is also presumed to be a cellular defence to silence foreign DNA transcription. Methylation of HPV is known to occur. Recent studies of HPV 16 and 18 have shown that the extent of methylation varies by region of the genome, and changes in the methylation patterns may be associated with the grade of neoplasia. Epigenetic changes could also occur through direct interaction between HPV and the cellular proteins involved in DNA methylation and chromatin remodelling, including histone deacetylase, DNA methyltransferase and p300 (reviewed in Whiteside et al 2008). Numerous genes [e.g. cadherin 1 (*CDH1*), fragile histidine triad gene (*FHIT*), telomerase reverse transcriptase (*TERT*), cadherin 13 (*CDH13*), O-6-methylguanine–DNA methyltransferase (*MGMT*), tissue inhibitor of metalloproteinase 3 (*TIMP3*) and hypermethylated in cancer 1 (*HIC1*)] have been demonstrated to be methylated in preneoplastic and neoplastic cervical tissue (reviewed in Wentzensen et al 2009). Currently, studies are underway to determine whether aberrant epigenetic changes are a prerequisite for HPV-mediated carcinogenesis.

Ovarian cancer

The majority of cases of ovarian cancer are not associated with familial predisposition. Although it is widely believed that ovarian epithelial tumours arise in the coelomic epithelium that covers the ovarian surface, there is now accumulat-

ing evidence suggesting that they could arise from tissues that are embryologically derived from the Müllerian ducts. The observation that women with a greater number of ovulatory cycles have an increased risk of ovarian cancer led to the incessant ovulation hypothesis by Fathalla in 1971. According to this hypothesis, as ovulation occurs, ovarian surface epithelial cells are internalized and damaged, and the subsequent repair mechanisms place the cells at an increased risk of developing mutations and subsequent malignancies. Consistent with this hypothesis, women with a history of multiple pregnancies, increased time of lactation and oral contraceptive use are at decreased risk. However, this theory is weakened by other observations. For example, endometriosis, the presence of endometrium outside the uterus, is associated with increased risk of ovarian cancer (Melin et al 2006). Likewise, hysterectomy (particularly at an early age) and tubal ligation, both of which result in either removal or alteration of Müllerian tissue, are associated with decreased risk of epithelial ovarian cancer (Irwin et al 1991, Hankinson et al 1993, Parazzini et al 1993, Narod et al 2001). The fact that a substantial residual risk for peritoneal cancer in *BRCA1* and *BRCA2* mutation carriers remains for a long time following prophylactic salpingo-oophorectomy (Finch et al 2006) supports the view that the cell of origin for ovarian cancer may originate from outside the ovary. Dubeau was the first to challenge the coelomic hypothesis (Dubeau 1999), as it is surprising that tumours currently regarded as being of primary ovarian origin would resemble tumours derived from various segments of the Müllerian tract (cervix, endometrium and fallopian tube), despite the fact that the ovary is not embryologically related to this tract. Proponents of the coelomic metaplasia hypothesis account for the Müllerian appearance of ovarian tumours by stipulating that the coelomic epithelium is not the direct precursor of ovarian tumours, but must first change into Müllerian-like epithelium by metaplasia. This implies that ovarian carcinomas are better differentiated than the cells from which they originate. This notion is at odds with our current understanding of cancer development (Dubeau 2008a).

Early events in ovarian carcinogenesis

Like most cancers, epithelial ovarian cancers are thought to arise from a single cell in 90% of cases. Evidence for the clonality of ovarian cancer lies in the similarity between primary and metastatic lesions during the examination of LOH, X-chromosome inactivation and specific gene mutations (reviewed in Landen et al 2008). In contrast to cervical cancer, where early changes can be studied due to the fact that the cervix is easily accessible, it is very difficult to identify early changes in ovarian carcinogenesis, even more so because the cell of origin is still under debate.

Studying genetic disorders can provide great insight into the aetiology and early events in carcinogenesis. As outlined above, hereditary genetic disorders account for approximately 10% of ovarian cancers, and 90% of these are either *BRCA1* or *BRCA2* mutations. In recent years, a major effort to prevent serous cancer in genetically susceptible women with mutations in *BRCA1* or *BRCA2* has spawned the practice of prophylactic salpingo-oophorectomy. Histological surveillance of prophylactic salpingo-oophorectomy specimens revealed that many early cancers in these women arise

in the fallopian tube, and further studies have pinpointed the distal (fimbrial) portion as the most common site of origin. In addition, a high proportion of histologically normal fimbriae from *BRCA* mutation carriers stain positive for *p53* (Crum et al 2007). Another convincing piece of molecular evidence favouring the idea that the cell of origin for ovarian cancer comes from the Müllerian duct is provided by recent expression profiling studies. Gene expression profiles of laser capture microdissected non-malignant distal fallopian tube epithelium from *BRCA1* and *BRCA2* mutation carriers and control women, as well as high-grade tubal and ovarian serous carcinoma, have been analysed (Tone et al 2008). Interestingly, fallopian tube samples from mutation carriers clustered closely with serous carcinomas rather than normal control fallopian tube epithelium. These findings support a common molecular pathway for adnexal serous cancers, and provide further evidence that cells from the Müllerian duct serve as the cells of origin for ovarian cancer. All this leaves us with the question of why *BRCA* mutation carriers do not carry an exaggerated high risk for endometrial cancer. The endometrium contains by far the highest number of epithelial cells originating from the Müllerian duct, and hence the statistical chances would be higher for a cancer in this organ rather than in the ovary, where cancers develop extremely frequently in *BRCA* mutation carriers. This paradox can be resolved by looking at the contribution of the stroma and the microenvironment to tumorigenesis. Dubeau's group inactivated the *BRCA1* gene in mouse granulosa cells (Chodankar et al 2005, Dubeau 2008b). Two-thirds of the mice developed epithelial cysts in their reproductive organs by the time they reached 12–18 months of age. Some of those cysts involved the ovary and were very similar to human ovarian cystadenomas. Although the tumours were benign, preliminary results suggested that crossing the mutant mice with mice carrying a homozygous knock-out of *p53* increases the rate of malignant transformation. The fact that the cystic tumours showed no evidence of rearrangement of *BRCA1*, implying that they expressed a functional *BRCA1* protein, strongly supports the view that the ovarian stroma — in particular, granulosa cells — influences the development of ovarian epithelial tumours (Chodankar et al 2005, Dubeau 2008b).

Most of the evidence on genetic and epigenetic alterations in ovarian cancer is based on studies of late-stage cancers. However, current understanding of these processes allows speculation that many alterations must occur early to achieve a clinically recognized tumour. The genetic and epigenetic abnormalities in ovarian cancer involve genes at each step in the complex pathway of cell regulation, which are summarized in Figure 35.1. These include involving growth factors [macrophage colony-stimulating factor, transforming growth factor (TGF)- β], growth factor receptors [*fms*, epidermal growth factor receptor (EGFR), *Her-2/neu*], genes involved in signal transduction (*ras*), genes involved in transcriptional regulation (*myc*, *p53*) and LOH at various loci, which occur in a proportion of epithelial ovarian cancers.

Oncogenes in sporadic ovarian cancer

Over 60 different oncogenes have been identified and they are categorized according to their cellular location and func-

tion. The subject is reviewed in detail by Landen et al (2008) and Barton et al (2008).

Growth signals

There is good evidence that the response of ovarian cancer cells to growth factors is altered. The proliferative response of ovarian cancer cells in culture to epidermal growth factor (EGF) and TGF- α is variable but usually less than normal ovarian epithelium (Berchuck et al 1990), whilst the inhibitory effect of TGF- β is less marked in ovarian cancer cell lines than in normal ovarian epithelium. TGF- β appears to function as an autocrine inhibitory factor in normal ovarian epithelial growth, and the loss of this regulatory loop may represent a step in the process of ovarian carcinogenesis. During early phases of carcinogenesis, antigrowth signals must be overcome. The restriction point after which a cell is committed to divide is controlled by cyclin D and E's regulation of E2F release by *Rb*. Cyclin E is overexpressed in malignant tumours and is associated with poor prognosis in early-stage ovarian cancer (Marchini et al 2008).

The initiation of DNA replication represents a final and critical step in growth regulation, and lies downstream at the convergence point of growth regulatory pathways (Williams et al 1998). Minichromosome maintenance proteins (Mcm2–7) participate in the assembly of prereplicative complexes to establish competence for initiation of DNA synthesis (DNA replication licensing). All six Mcm proteins are essential for replication, are present in all phases of the proliferative cell cycle, but are tightly downregulated in the quiescent, terminally differentiated and senescent 'out-of-cycle' states. The presence of one protein reflects the presence of the other five, as all six are loaded together on to DNA as a heterohexamer on exit from metaphase. Mcm proteins have not been shown to be good prognostic markers in ovarian cancer (Gakiopoulou et al 2007, Marchini et al 2008).

Telomeres are tandem repeats of a short DNA sequence at the end of each chromosome. The length of telomeres decreases in somatic cells each time they divide. Most mammalian cells are therefore limited in terms of the number of times they can undergo cell division, because chromosomes cannot replicate unless their telomeres are longer than a minimal critical length. This mitotic clock does not operate in cancer cells because almost all cancers express telomerase, ensuring maintenance of the telomeres above the critical length necessary to support cell division, activating *p53* and other policing proteins that propel a cell into an apoptotic pathway. Most ovarian cancer cells maintain telomere length by production of telomerase, a reverse transcriptase composed of an RNA component (hTR) and a catalytic subunit (hTERT). The hTR subunit is expressed by all cells, but hTERT expression increases with increasing tumorigenicity, which suggests that it is the rate-limiting step in telomerase activity (reviewed in Landen et al 2008).

Growth factor receptors

The growth factor receptors are a family of cell membrane tyrosine kinases which act as receptors for growth factors and are involved in signal transduction via autophosphorylation and phosphorylation of intracellular proteins. EGFR

(also referred to as *erbB*) and *Her-2/neu* (also referred to as *erbB2*) are structurally similar, and both have been shown to be overexpressed in human cancers. *EGFR* is expressed by most advanced-stage ovarian cancers and there is some evidence that *EGFR*-positive tumours have a worse prognosis than tumours that do not express the receptor. *Her-2/neu* is overexpressed in approximately one-third of ovarian cancers (Slamon et al 1989), and overexpression is associated with gene amplification. Many proliferation pathways mediate signals through the *RAS* (rat sarcoma viral oncogene homolog) oncoprotein, a G-protein attached to the cell membrane and activated by many tyrosine kinase receptors, and *BRAF* (v-*raf* murine sarcoma viral oncogene homolog B1), which is downstream of *RAS*. *RAS* activates a cascade of serine/threonine and tyrosine non-receptor kinases, which leads to phosphorylation and activation of *Erk1* and *Erk2* transcription factors that make their way to the nucleus to initiate signals of growth and progression through the cell cycle. *RASSF1A* (Ras association domain family 1 isoform A) is a recently discovered tumour suppressor whose inactivation — mainly by DNA methylation (Barton et al 2008) — is implicated in the development of many human cancers. *RASSF1A* lacks apparent enzymatic activity but contains a Ras association domain and is potentially an effector of the Ras oncoprotein. *RASSF1A* modulates multiple apoptotic and cell cycle checkpoint pathways. Current evidence supports the hypothesis that it serves as a scaffold for the assembly of multiple tumour suppressor complexes, and may relay proapoptotic signalling by *K-ras*.

Oncogenes

Chromosome 3q26 is found to be increased in copy number in approximately 40% of ovarian cancers. This region contains a recently identified oncogene, *PIK3CA*, which encodes the p110- α subunit of phosphatidylinositol 3-kinase (PI 3-kinase). PI 3-kinase-mediated signalling is involved in a broad range of cancer-related functions, including glucose transport, catabolism, apoptosis, cell adhesion, *RAS* signalling and oncogenic transcription. Little is known about the role of most nuclear oncogenes in ovarian cancer. Amplification of *c-myc* and increased expression of the protein product has been described in approximately one-third of ovarian cancers. Overexpression of *c-myc* is found in 38% of ovarian tumours (Tashiro et al 1992).

Tumour suppressor genes in sporadic ovarian cancer

Mutations of the *p53* gene are the most frequent genetic alterations in cancer, and occur most frequently in regions of the gene which show the greatest degree of conservation between *p53* proteins of different species. Immunohistochemical studies have revealed overexpression of the *p53* protein in 50% of advanced-stage ovarian cancers (Marks et al 1991). Sequencing of *p53* from ovarian cancers overexpressing the *p53* protein has, in most cases, confirmed point mutations in conserved regions of the gene (Marks et al 1991). In most of these tumours, LOH studies have revealed that the second copy of the gene is inactivated through deletion of the gene. *p53* mutations are less common in stage I disease than advanced-stage disease, and clonal analysis suggests that the occurrence of *p53* mutations precedes but is

temporally associated with metastases (Jacobs et al 1992). No clear relationship between *p53* mutation and histological grade or prognosis has been established. The location and nature of *p53* mutations in ovarian cancer have now been reported in 149 tumours. Over 100 different mutations involving approximately 60 different codons have been identified, and most occur in the highly conserved exons 5–8 of the gene. The codons most frequently involved in *p53* mutations are the same as those described in other cancers. The pattern of mutations suggests that most *p53* alterations in ovarian cancer arise due to endogenous mutagenic processes rather than exposure to a carcinogen.

Several novel potential candidate tumour suppressor genes have recently been reported for ovarian cancer, and their role in ovarian carcinogenesis has yet to be elucidated. Analysis of LOH at 11q25 identified *OPCML* (opioid binding protein/cell adhesion molecule-like), a member of the IgLON family of immunoglobulin domain-containing glycosylphosphatidylinositol-anchored cell adhesion molecules, as a candidate tumour suppressor gene in ovarian cancer (Sellar et al 2003). *OPCML* is frequently somatically inactivated by allele loss, and up to 83% of ovarian cancers demonstrate CGI methylation of this gene.

Defects in programmed cell death can promote oncogenesis and resistance to chemotherapy. Apoptosis (type I programmed cell death) has been well studied as a caspase-regulated cellular response to environmental stress and to the activation of oncogenes. Numerous genes involved in apoptosis are methylated and silenced in ovarian cancer (Barton et al 2008, Figure 35.3). Autophagy (type II programmed cell death) is characterized by the accumulation of multilamellar vesicles that engulf cytoplasm and organelles, forming autophagosomes marked by microtubule-associated protein light chain 3. The maternally imprinted Ras-related tumour suppressor gene, *aplasia Ras* homolog member I (*ARHI*), is downregulated in more than 60% of ovarian cancers, and re-expression of *ARHI* in multiple human ovarian cancer cell lines induces autophagy (Lu et al 2008). In addition, death-associated protein kinase (*DAPK*) also contributes to the autophagic pathways, and loss of their function — a feature frequently observed in ovarian cancer — could inhibit the induction of autophagy and increase the incidence of cancer.

Loss of heterozygosity

Studies of LOH in ovarian cancer have revealed a number of regions with high frequencies of loss. The reported frequency of LOH for each chromosome arm is summarized in Figure 35.6. Losses have been observed on almost all chromosome arms, and the background 'random' rate of loss in ovarian cancer is high (range 15–25%). A high frequency of allelic deletion (>33%) based upon more than 50 tumours in at least three separate studies has been documented for seven chromosome arms: 6p, 6q, 13q, 17p (possibly associated with *p53*), 17q, 18q and Xp. A number of other chromosome arms have frequencies of loss in the range 25–33% which may be above background rates: 4p, 8p, 9p, 9q, 11p, 14q, 16q, 19p and 21q and 22q (McCluskey and Dubeau 1997). Some of these allelic deletions have been correlated with clinicopathological parameters. Recent studies have shown a distinct relationship between allelic

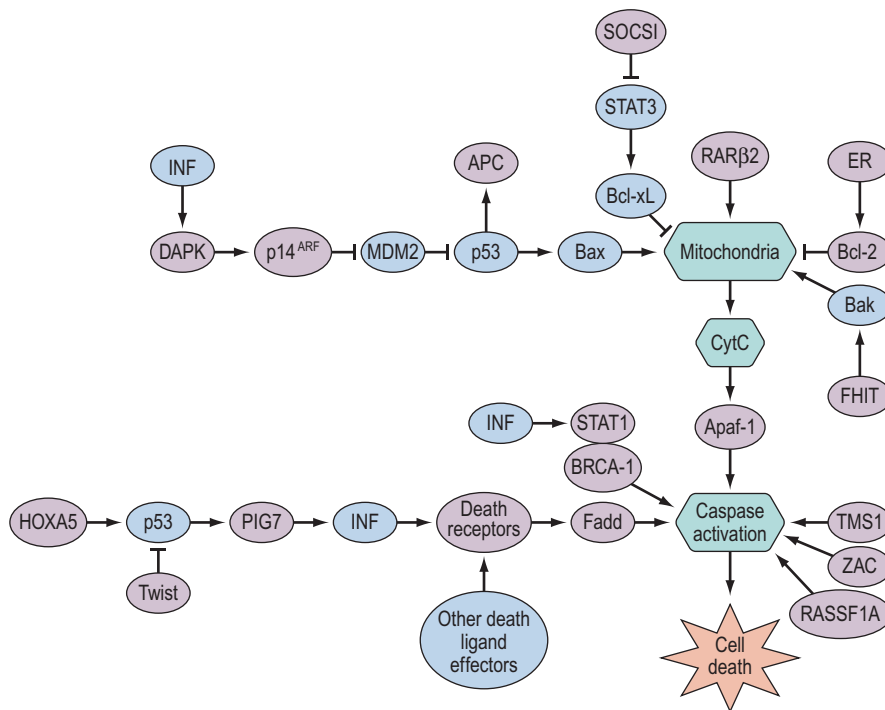

Figure 35.6 Genes which are involved in the cascade which leads to programmed cell death (apoptosis). Genes in red have a CpG island and can be silenced by means of DNA methylation.

imbalance at 8p12-p21 and 8p22-pter in ovarian cancer and tumour grade, stage and histological subtype. Poorly differentiated tumours, advanced-stage cancers and serous tumours were more prone to allelic imbalance at these regions (Pribill et al 2001).

Further localization of putative tumour suppressor genes in regions with a high rate of LOH requires detailed analysis with a panel of polymorphic markers for the relevant chromosome arm. Available data suggest that a number of as yet unidentified tumour suppressor genes are involved in ovarian carcinogenesis, and recent reports have defined deletion units on chromosome arms with the highest rates of LOH including 6p, 6q, 11p, 13q, 17q and Xp. The nature of specific chromosomes affected by LOH can influence tumour biological aggressiveness, as losses on certain chromosomes such as 13q and Xq are strongly associated with poorly differentiated tumours (Cheng et al 1996). LOH in chromosomes 6q or 17 is more frequently found in well-differentiated tumours.

Comparative genomic hybridization

The application of this technique has shown that 53–69% of human ovarian cancers demonstrate amplifications on chromosomes 1q, 3q, 8q, 13q, 19p and 20q (Kiechle et al 2001). Under-representations were found for chromosomes 4q, 13q and 18q in approximately 50% of ovarian cancers. Undifferentiated tumours were found to correlate significantly with under-representation of 11p and 13q, as well as with amplification of 7p and 8q.

cDNA microarrays

The development of cancer is the result of a series of molecular changes at DNA level, and these events lead to changes in gene expression (mRNA) levels of numerous

genes resulting in different phenotypic characteristics of tumours. cDNA microarray analysis enables the identification of differences in gene expressions between normal and malignant tissues by analysing thousands of genes at the same time. A recent study comparing 5766 different gene expressions between normal and malignant ovarian tissue revealed that several genes were under- or overexpressed (Wang et al 1999). Several genes were highly overexpressed in ovarian cancer, such as epithelial glycoprotein (GA733, gene antigen 733), *PUMP1* (Pump-1 protease) (*MMP7*, matrix metalloproteinase 7) and *cytokeratin 8*, and some of these have also been shown to be overexpressed in other cancers such as colorectal cancer. This illustrates that phenotypic similarity between different tumour types is also reflected at molecular level.

Another study, using a DNA microarray of 9121 genes, identified 55 genes commonly upregulated and 48 genes downregulated in ovarian cancer specimens compared with the corresponding normal ovarian tissues (Ono et al 2000). The 55 genes that were often upregulated in the nine adenocarcinomas analysed represent candidates for stimulating cell growth and preventing apoptosis. Serial analysis of gene expression has recently been introduced to generate global gene expression profiles from various ovarian cell lines and tissues including primary ovarian cancers, ovarian surface epithelial cells and cystadenoma cells. More than 56,000 gene expressions (10 different libraries) were generated (Hough et al 2000). Interestingly, ovarian cancer cell lines showed high levels of similarity to libraries from other cancer cell lines such as colorectal cancer, indicating that these cell lines had lost many of their tissue-specific expression patterns. Many of the genes upregulated in ovarian cancer represent surface or secreted proteins such as mucin-1, HE4 (human epididymal protein 4), epithelial cellular adhesion molecule, mesothelin and several keratins (e.g. keratins 18 and 19).

MicroRNAs

MicroRNAs (miRNAs) are endogenous non-coding small RNAs which negatively regulate gene expression. In human cancer, miRNAs might function as either oncogenes or tumour suppressor genes. Increasing evidence shows that expression of miRNAs is deregulated in human cancer. High-throughput miRNA quantification technologies have provided powerful tools to study global miRNA profiles. It has become progressively obvious that although the number of miRNAs (~600) is much smaller than that of the protein-coding genes (~22,000), miRNA expression signatures reflect the developmental lineage or tissue origin of human cancers more accurately. Recently, it has been demonstrated that genomic copy number loss and epigenetic silencing, respectively, may account for the downregulation of ~15% and at least ~36% of miRNAs in advanced ovarian tumours, and miRNA downregulation contributes to a genome-wide transcriptional deregulation. Eight miRNAs located in the chromosome 14 miRNA cluster (Dlk1-Gtl2 domain) were identified as potential tumour suppressor genes. Tumours with lower expression of these eight miRNAs were associated with a higher proliferation index and significantly shorter survival. Although the function of this miRNA cluster is largely unknown, it may play a critical role in embryonic development (Zhang et al 2008).

DNA methylation

As outlined above, genome-wide demethylation of normally methylated and silenced chromosomal regions, and hypermethylation and silencing of genes including tumour suppressors are among the most common features of cancer cells (reviewed in Barton et al 2008). Epigenetic alterations, including CGI DNA methylation, frequently occur in ovarian cancer, and the identification of specific genes that are altered by epigenetic events is currently an area of intense research. Aberrant DNA methylation in ovarian cancer is observed in early cancer development, can be detected in serum/plasma DNA and hence provides the promise of a non-invasive cancer detection test. In addition, identification of ovarian-cancer-specific epigenetic changes has promise in molecular classification and disease stratification.

Endometrial cancer

Endometrial cancers have long been classified into two major divisions (types I and II) based on light microscopic appearance, clinical behaviour and epidemiology. Type I (endometrioid histology) comprise 70–80% of newly diagnosed cases of endometrial cancer. They are associated with unopposed oestrogen exposure and are often preceded by premalignant disease (atypical complex hyperplasia). In contrast, type II endometrial cancers (usually papillary serous or clear cell histology) have not been identified in association with hormonal factors, and do not have a readily observed premalignant phase. In addition, they demonstrate an aggressive clinical course compared with the type I tumours. The morphologic and clinical differences are paralleled by genetic distinctions, in that type I and II cancers carry mutations of independent sets of genes (Hecht and Mutter 2006). While most type II cancers contain mutations of *p53*, type I adenocarcinomas demonstrate larger numbers

of genetic changes in which the temporal sequence of mutation and the final combination of defects differ substantially between individual examples. Common genetic changes in endometrioid endometrial cancers (type I) include, but are not limited to, microsatellite instability or specific mutation of *PTEN* (phosphatase and tensin homolog), *K-ras* and *β-catenin* genes (Hecht et al 2006). With regard to epigenetics, promoter hypermethylation is common in type I but not type II tumours. Many of the tumour suppressor pathways that are mutated in type I endometrial cancer such as *PTEN*, *hMLH1*, *MGMT* and *APC* can also be inactivated by hypermethylation. In addition, *PR-B* (progesterone receptor B) promoter hypermethylation is established as the dominant mechanism of *PR-B* silencing (Zhou et al 2007).

Vulval cancer

Neoplasias of the vulva are rare malignancies accounting for less than 5% of all female genital tract cancers. However, in recent years, the incidence of vulval intraepithelial neoplasia (VIN), a precursor of vulval cancer, has increased in young women, generating considerable interest in its molecular pathogenesis.

CGH has recently been used to study alterations (losses or gains) on all chromosomes in vulval cancer (Jee et al 2001). Frequent chromosomal losses were found on 3p, 4p13-pter and 5q, and less frequent losses were found on 6q, 11q and 13q. Most frequent chromosomal gains were observed on 3q and 8p, and less frequent gains were found on 9p, 14, 17 and 20q. The pattern of chromosomal imbalance in vulval cancer detected by CGH was revealed to be very similar to that in cervical cancer. These results suggest that the molecular pathways in vulval and cervical carcinomas may be similar. However, it is not clear whether HPV-positive and -negative vulval cancers have similar or different molecular pathways.

Vulval squamous cell carcinomas (VSCCs) exhibit a broad range of allelic losses irrespective of HPV status, with high frequencies of LOH on certain chromosomal arms. High frequencies of LOH are found on 1q, 2q, 3p, 5q, 8p, 8q, 10p, 10q, 11p, 11q, 15q, 17p, 18q, 21q and 22q (Pinto et al 1999). This suggests that despite their differences in pathogenesis, both HPV-positive and -negative VSCCs share similarities in type and range of genetic losses during their evolution. Another study observed a greater number of molecular alterations in HPV-negative vulval cancers compared with HPV-positive tumours (Flowers et al 1999). Allelic losses at 3p are common early events in vulval carcinogenesis in HPV-negative cancers, and are detected at a high rate in the corresponding high-grade precursor lesions (VIN II/III). *TP53* gene mutations with associated 17p13.1 LOH are also more common in HPV-negative cancers. Fractional regional loss index, an index of total allelic loss at chromosomal regions 3p, 13q14 and 17p13.1, is greater in HPV-negative vulval cancers than in HPV-positive tumours (Flowers et al 1999). Similar observations have been found in HPV-negative high-grade VINs compared with HPV-positive lesions. Overall, LOH at any 3p region is common (80%) in both groups of cancers and in their associated VIN lesions. Although *TP53* gene mutations are present in a minority of vulval cancers (20%), allelic losses at the *TP53* locus are frequently present,

especially in HPV-negative vulval cancers, compared with HPV-positive tumours.

Fallopian tube cancer

The histological features, and biological and clinical behaviour of fallopian tube cancer are similar to those of ovarian cancer. In addition, there is recent evidence that similar genetic alterations occur with the same frequency between fallopian tube and ovarian cancer when considering the same histological subtype. This suggests a common molecular pathogenesis between these cancer types (Crum et al 2007). Recent molecular genetic analyses using CGH reveal that different histological subtypes differ in respect to their genomic alterations, but similar subtypes of different cancers have similar patterns of genomic abnormalities. For example, the frequency and pattern of chromosomal changes detected in serous tubal carcinomas (95% of all fallopian tube carcinomas) are strikingly similar to those observed in serous ovarian carcinomas, suggesting a common molecular pathogenesis. In fallopian tube carcinoma, frequent gains are found on chromosomes 3q and 8q and frequent losses are found on chromosomes 4q, 5q, 8q and 18q (Pere et al 1998). There is also evidence that fallopian tube cancer is similar to ovarian cancer with respect to the proportion of tumours with abnormal expression of *Her-2/neu* and *p53*. The prognostic significance and predictive drug response of these two genes needs to be explored in fallopian tube cancer.

Clinical Aspects of the Genetics of Gynaecological Cancer

Cancer prevention

Vaccines against HPV have become available over the last few years. Two HPV vaccines — a quadrivalent vaccine against HPV types 6, 11, 16 and 18 (Gardasil) and a bivalent vaccine against HPV types 16 and 18 (Cervarix) — are now licensed in the European Union for the prevention of pre-malignant cervical lesions and cervical cancer. The quadrivalent vaccine is also licensed for prevention of premalignant vulval and vaginal lesions, and external genital warts. Both vaccines show high efficacy in preventing high-grade pre-malignant cervical lesions. Studies to date have been too brief to confirm the effectiveness of the vaccines for the prevention of cervical cancer. There are also uncertainties about the duration of protection, whether booster doses are needed and whether the vaccines protect against infection with non-vaccine HPV types. A national programme to vaccinate girls aged 12–13 years began in the UK in September 2008.

Early detection of cancer

Knowledge of specific genetic and epigenetic alterations associated with cancer, along with the high sensitivity of molecular techniques such as the polymerase chain reaction, may provide new methods for detection of cancer. As direct sampling of the ovary requires an invasive procedure, any screening test for ovarian cancer based upon genetic markers will be directed towards identification of a gene product in peripheral blood. Tumour-specific hypermethylation of at

least one of a panel of six tumour suppressor gene promoters, including *RASSF1A* (Ras association domain family member 1A), *BRCA1* (breast cancer 1 early onset), *APC* (adenomatous polyposis coli), *CDKN2A* (cyclin-dependent kinase inhibitor 2A) and *DAPK* (death-associated protein kinase 1), could be detected in the serum or plasma of ovarian cancer patients with 100% specificity and 82% sensitivity, including 13/17 cases of stage I (confined to the ovary) disease. Methylation was only observed in one peritoneal fluid sample from 15 stage IA or B patients, but 11/15 paired sera were positive for methylation (Ibanez de Caceres et al 2004). In addition to proof of principle, these data indicate that circulating ovarian tumour DNA is more readily accessible in the bloodstream than in the peritoneum. In addition, serum DNA methylation of *SFRP1* (secreted frizzled-related protein 1), *SOX1* (SRY (sex determining region Y)-box 1) and *LMX1A* (LIM homeobox transcription factor 1 alpha) revealed sensitivity and specificity of 73% and 75%, respectively (Su et al 2009).

DNA is a very stable molecule compared with RNA or protein. It can easily be analysed in any body fluid, including vaginal secretions. In a proof of principle study, the authors aimed to define a new and simple strategy for detection of endometrial cancer using epigenetic markers. They investigated DNA isolated from vaginal secretions collected from tampons for aberrant methylation of five genes [*CDH13*, *HSPA2* (heat shock 70kDa protein 2), *MLH1*, *RASSF1A*, and *SOCS2* (suppressor of cytokine signalling 2)] using MethyLight in 15 patients with endometrial cancer and 109 patients without endometrial cancer. All endometrial cancer patients revealed three or more methylated genes, whereas 91% (99 of 109) of the patients without endometrial cancer had fewer than three genes methylated in their vaginal secretion. The methods developed in this study provided the basis for a prospective clinical trial to screen asymptomatic women who are at high risk for endometrial cancer (Fiegl et al 2004).

Prognostic and predictive indicators

Numerous genetic and epigenetic prognostic and predictive markers have been discovered over the past few years (reviewed in Crijns et al 2006, Barton et al 2008), but none of these markers have yet been integrated into clinical practice. Silencing of *hMLH1*, a DNA mismatch repair gene, by hypermethylation of its promoter CGI has been linked with acquired resistance to platinum-based drugs in ovarian cell line models. Moreover, methylation of *MLH1* is increased at relapse in epithelial ovarian cancer patients, with 25% (34/138) of plasma samples from relapsed patients showing methylation of *MLH1* which is not evident in matched prechemotherapy plasma samples (Barton et al 2008). The acquisition of *MLH1* methylation at relapse predicts poor overall patient survival, and is associated with drug resistance (Gifford et al 2004, Barton et al 2008). The concept of predicting and monitoring response to systemic therapies by means of serum/plasma DNA analysis is currently under investigation.

Strategies for gene therapy

Promising preclinical and clinical data led to the initiation of an international randomized phase II/III trial of *p53* gene

therapy for first-line treatment of patients with ovarian cancer. In that trial, replication-deficient adenoviral vectors carrying wild-type *p53* were given intraperitoneally in combination with standard chemotherapy to patients with ovarian cancers harbouring *p53* mutations. The study was closed after the first interim analysis because an adequate therapeutic benefit was not shown (Zeimet and Marth 2003). There may be various reasons for the failure of this strategy; for example, the repair of single genes might not be a suitable strategy for the treatment of cancer, heterogeneity or

lack of expression of coxsackie-adenovirus receptors and integrin coreceptors in ovarian tumours, and the presence of adenovirus-neutralizing antibodies in ovarian cancer-related ascites. Although the safety of many other treatment strategies has been demonstrated in early-phase clinical trials, efficacy has been mostly limited. Major challenges include improving the vectors used, with the aim of more effective and selective delivery. In addition, effective penetration into and spreading within advanced and complex tumour masses and metastases remains challenging (Kanerva et al 2007).

KEY POINTS

1. Oncogenes result in a gain in function which will take effect even in the presence of the remaining normal copy of the gene; tumour suppressor genes involve a loss of function that requires inactivation or deletion of both copies of the gene before cellular regulation is affected.
2. Epigenetic events, particularly silencing of tumour suppressor genes by DNA methylation, are early key events in carcinogenesis.
3. The genetic changes required for cancer usually occur in the somatic cells and are random events. However, some individuals develop oncogenic mutations in their germ cells which can then be passed on to their progeny.
4. Among gynaecological cancers, inherited malignancies only occur in the ovary, endometrium and breast. These are rare, accounting for less than 5% of ovarian or endometrial cancers.
5. Two genes, termed *BRCA1* and *BRCA2*, have been identified. *BRCA1* is found in almost all families with both breast and ovarian cancer, and in 40% of families with breast cancer alone.
6. These genes have high penetrance, with 80% of affected individuals developing a malignancy between 30 and 70 years of age.
7. Genetic advice to women who may have inherited a cancer gene should only be given by clinical geneticists or gynaecological oncologists with a special knowledge of these conditions.
8. The efficacy of screening such women is unproven. There is a substantial risk of false-positive results.
9. Oophorectomy and hysterectomy should be considered if the risk of inheritance seems high.
10. Identifying the genetic basis for cancer allows for the investigation and development of therapy targeted at the underlying abnormality.

Principles of radiotherapy and chemotherapy

Nawaz Walji and Indrajit Fernando

Chapter Contents			
RADIOTHERAPY	539	KEY POINTS	553
CHEMOTHERAPY	547		

Radiotherapy

Radiotherapy is the utilization of ionizing radiation, primarily for the treatment of malignant cancers and infrequently for some preinvasive and benign conditions. It is central to the curative treatment of women with cervical carcinoma, and is used in the adjuvant and palliative treatment of other gynaecological malignancies.

Radiation physics

Therapeutic ionizing radiation can be electromagnetic or particulate. Particulate radiation causes ionization directly and electromagnetic radiation indirectly by ejecting fast-moving electrons from atoms, resulting in potentially significant biochemical, cellular and tissue changes within biological systems. Radiation energy absorbed in tissue is measured in grays (Gy), with 1 Gy being equivalent to 1 joule per kilogram.

Electromagnetic radiation

X-rays and gamma-rays (γ -rays) are part of the electromagnetic spectrum; the former are produced artificially and the latter from naturally occurring or artificially produced radioisotopes. Megavoltage X-rays for therapeutic purposes are produced by a linear accelerator (Figure 36.1) by accelerating electrons to high kinetic energies on to a target composed of tungsten or gold. Kinetic energy given up by the electrons is converted to high-energy X-rays. γ -rays are emitted as byproducts of radioactive isotopes (e.g. iridium-192) undergoing decay to reach a stable nuclide.

X-rays and γ -rays are characterized by very short wavelengths and high frequencies, and consist of packets of energies (photons) capable of tissue ionization. Higher energy photons have greater tissue penetration. Photon energies in the range of 6–15 million electron volts (megavolts, MV) are typically used for pelvic irradiation, although higher energies may be required for obese patients to achieve adequate dose to the centre of the pelvis. Use of photon energies less than 4 MV can result in greater dose variation within the patient.

Particulate radiation

This consists of atomic subparticles: electrons (negatively charged), protons (positively charged), neutrons (no charge) and negative π -mesons. Only electrons are commonly used in clinical practice. High-energy electrons are produced in a linear accelerator from which the target has been removed. Electrons react more rapidly with tissue compared with photons, and have a depth-dose profile which follows a plateau for a distance depending on the electron energy, followed by a rapid dose fall-off. Electrons are useful for the treatment of superficial tumours, allowing sparing of deeper structures which reduces treatment-related morbidity.

Proton beam radiotherapy has generated increasing interest in recent years. The dose distribution of a monoenergetic proton beam increases slowly with depth but reaches a sharp maximum near the end of the particle's range (Bragg peak) with subsequent rapid dose fall-off. This has the attraction of precisely confining the high-dose region to the deep-seated tumour volume whilst minimizing the dose to the surrounding normal tissues. The availability of proton beam therapy remains restricted by the limited number of cyclotron machines available globally for the production of protons.

Radiobiology

Radiobiology is the study of the effects of ionizing radiation on biological systems. Ionizing radiation acts on both normal and cancer cells. The primary ionization event in living cells usually occurs within intracellular water molecules, with subsequent ionization occurring in surrounding macromolecules. Deoxyribose nucleic acid (DNA) is the critical intracellular target for radiation therapy. Following DNA damage, some cells undergo immediate apoptosis. More frequently, death occurs at subsequent mitosis and the main effect of radiation is to delay or prevent mitosis. The onset of the latter depends on the cellular turnover time, hence more rapidly dividing systems (e.g. intestinal epithelium) show the effects of radiation earlier compared with slowly dividing systems (e.g. central nervous system).

Figure 36.1 A linear accelerator and radiotherapy treatment room. The linear accelerator can rotate 360° around the treatment couch, which is also able to rotate about its axis, allowing the patient to be treated using beams from multiple directions. The patient is monitored during treatment using cameras, and communication is possible using a microphone.

Eradication of a cancer is only possible if irreversible DNA damage in all tumour clonogens is achieved. The success or otherwise of ionizing radiation in achieving this is governed by the five 'Rs' of radiobiology: reoxygenation, redistribution, repair, repopulation and (intrinsic) radiosensitivity. *Intracellular oxygen* is important for the ionizing effects of radiation, and total hypoxia results in a dose reduction of a factor of 2–3 in most biological systems. *Reoxygenation* of hypoxic cells occurs as a consequence of tumour regression during fractionated radiotherapy, resulting in increased radiation efficacy. Anaemia is a poor prognostic factor in the treatment of cervical carcinoma, and is thought to relate to reduced oxygen partial pressures secondary to a low haemoglobin concentration. Patients having radiotherapy for cervical carcinoma should have their haemoglobin concentration maintained above 12 g/dl. *Redistribution* of cells into the cell cycle from the resting phase during a course of fractionated radiotherapy increases the number of cells undergoing mitotic division, increasing the probability of tumour cell kill. Despite radiation, some tumour clonogens may undergo successful *repair* of DNA damage, and subsequent *repopulation* of these cells results in treatment failure. Finally, *intrinsic radiosensitivity* is an inherent property of tumours; some tumours (e.g. lymphomas) are successfully eradicated with relatively low doses of radiotherapy, whilst others (e.g. gliomas) frequently recur despite high radiation doses. Indirect effects of radiation on tumours include loss of small blood vessels leading to tumour necrosis and subsequent activation of the reticuloendothelial system.

A major challenge for radiotherapists is to eradicate tumours without causing significant permanent damage to normal tissue. Three important factors need consideration when planning a radical course of radiation: the total dose of radiation required to achieve tumour eradication, the number of fractions required to deliver the total dose, and the length of time over which the treatment is delivered. Normal tissues have a greater capacity for repair of sublethal DNA damage compared with cancer cells, provided that the

overall dose is not too large and is given over a period of time. However, significant prolongation of treatment increases the risk of treatment failure for some cancers, including squamous cell carcinoma of the cervix. Advantages of fractionated radiotherapy include:

- repair of DNA damage and repopulation of cells in normal tissues between treatment fractions;
- recruitment of cancer cells from the resting phase into the more radiosensitive phases of the cell cycle; and
- reoxygenation of hypoxic tumour cells following tumour regression.

Normal tissue tolerance is an important concept in radiotherapy. Accepted tolerance ranges of total radiation dose which result in a clinically acceptable low incidence of treatment-related morbidity have been established. A number of factors adversely influence the radiation tolerance of normal tissues, including: volume of tissue irradiated, previous surgery, exposure to previous or concomitant cytotoxic treatment, vascular insufficiency, diabetes mellitus and connective tissue disorders.

Concomitant chemoradiation

Cisplatin-based chemoradiation became the standard of care in cervical cancer following an alert issued by the National Cancer Institute in 1999. The benefit of chemoradiation in cervical cancer over radiotherapy alone has been confirmed by recent meta-analyses. Concomitant chemotherapy may have an additive or synergistic effect when combined with radiotherapy. Perceived benefits include increased tumour sensitization to radiotherapy and eradication of systemic micrometastatic disease.

Radiation dose and scheduling

Radiotherapy fractionation

Conventional practice involves once-daily treatment giving five fractions per week using 1.8–2 Gy/fraction. Modified dose-fractionation schedules have been investigated in an attempt to improve cure rates. Hyperfractionated radiotherapy is the delivery of two or more fractions per day using smaller doses per fraction to deliver a higher total dose over the same time period compared with standard fractionated radiotherapy. An interfraction gap of a minimum of 6 h is recommended for recovery of normal cells. Advantages of this approach include delivery of a higher total dose to improve tumour eradication whilst allowing sufficient time for normal tissue repair between fractions. Accelerated radiotherapy refers to the delivery of radiotherapy over a significantly shorter period of time by delivering six or more fractions per week, with an interfraction gap of a minimum of 6 h. The total dose and dose per fraction remain the same as for standard treatment. Delivering radiotherapy over a shorter period of time reduces the negative effects of accelerated repopulation seen in some cancers. Hypofractionated radiotherapy delivers radiation treatment over a shorter period of time by using fraction sizes larger than 2 Gy/fraction. However, such an approach increases the risk of late normal tissue toxicity, as normal tissues are more sensitive to larger doses per fraction compared with tumour cells. In order to reduce this risk, the total dose of radiotherapy is

reduced to deliver the same biologically effective dose. Hypofractionated radiotherapy is commonly used in palliative radiotherapy to minimize patient inconvenience and to optimize resource utilization.

Dose prescription

A radiotherapy prescription specifies the total dose to be given, the total number of fractions to be used, the dose per fraction, and the overall treatment duration. The total dose required to eradicate a tumour is dependent on the tumour volume to be treated. Whereas a dose of 50 Gy in 25 fractions treating five times per week over 5 weeks is sufficient to eradicate microscopic disease in 90% of cases, doses above 66 Gy using 2 Gy/fraction over 6.5 weeks are required to eradicate macroscopic disease. Where delivery of radical radiotherapy with curative intent is not possible because of tumour-related (e.g. tumour volume, metastatic disease) or patient-related (e.g. poor performance status) factors, palliative radiotherapy may be considered to alleviate distressing symptoms. Doses typically used include 8 Gy in a single fraction, 20 Gy in five fractions over 1 week or 30 Gy in 10 fractions over 2 weeks.

Radiotherapy techniques

Teletherapy, also referred to as 'external beam radiotherapy', and brachytherapy are commonly utilized in the treatment of gynaecological malignancies and are discussed below. Instillation of radioactive fluids into the peritoneal or pleural cavity for treating small volume disease is rarely used and will not be discussed in detail.

External beam radiotherapy

This is irradiation of tumours at a 'long' distance away from the source of ionizing radiation. Pelvic external beam radiotherapy remains integral to the treatment of gynaecological malignancies as it permits irradiation of the primary tumour and regional lymph nodes. The dose that can be delivered to the tumour is limited by the tolerance of the normal tissues, also referred to as the 'organs at risk', which include the small bowel, rectum and bladder. Technological advances in the methods of radiation delivery are increasingly permitting the use of techniques which minimize the dose received by normal tissues whilst allowing a higher dose to be delivered to the tumour. Radiotherapy treatment planning remains a vital component of radiation treatment.

Radiotherapy planning

The aim of radiotherapy planning is to deliver a homogeneous dose to the primary tumour and potential areas of micrometastatic disease whilst minimizing the dose to the organs at risk. Accurate tumour localization is central to radiotherapy planning, and it is important to have the following information to hand: findings of clinical examination including examination under anaesthesia, operation notes and intraoperative findings, histopathology report and the results of any radiological investigations including computed tomography (CT), magnetic resonance imaging (MRI) and ¹⁸FDG-positron emission tomography (PET) scans.

Simulator-based radiotherapy planning has been superseded by CT-based planning which allows more accurate visualization of the tumour and organs at risk. Where appropriate, coregistration of MRI and CT images provides greater certainty and clarification of anatomy. Coregistration of functional imaging scans (e.g. PET scan) with planning CT scans may provide yet more sophisticated radiotherapy planning. The simulator — a diagnostic X-ray machine connected to a television screen which emulates a treatment machine — continues to have a useful role for palliative radiotherapy planning. It is also useful in the minority of cases where CT scanning is not possible due to patient obesity or other patient-related factors.

Planning procedure

A vaginal examination is performed prior to the CT scan to determine the extent of vaginal involvement and the most inferior aspect of the tumour. The patient is scanned in the supine position unless a belly board is used to displace the small bowel anteriorly to minimize small bowel irradiation, in which case she is placed in the prone position. A vaginal probe can aid in defining the extent of vaginal involvement, although this is not universally utilized. Rectal contrast may be used to delineate the rectum and sigmoid. Intravenous contrast may be administered to enhance identification of blood vessels which are anatomical landmarks for the regional lymph nodes. A CT scan is performed using 2.5–5-mm slices from the third lumbar vertebra to 5 cm below the ischial tuberosities. The superior border is extended to include the lower thoracic vertebrae if para-aortic lymph node irradiation is required. The patient is asked to have a comfortably full bladder to reduce the volume of small bowel within the pelvis. Following acquisition of CT images, permanent tattoos are marked on the patient's skin as reference points for aligning her in the correct position for each fraction of treatment.

Conformal radiotherapy

The CT scan images are subsequently transferred to a computer terminal (Figure 36.2) with software allowing delineation of target volumes and organs at risk according to recommendations from the International Commission on Radiation Units and Measurements. The gross tumour volume includes the palpable and/or radiologically visible tumour; it is absent if it has been surgically resected. The clinical target volume (CTV) involves the gross tumour volume and potential areas of microscopic disease (e.g. pelvic lymph nodes and parametria in cervical cancer). The CTV is grown by a margin to allow for internal organ motion and geometric uncertainties in treatment delivery; this is called the 'planning target volume' (PTV). The organs at risk for pelvic radiation include the rectum, bladder, small bowel and both hip joints. The kidneys and spinal cord are the dose-limiting organs at risk when radiating the para-aortic lymph nodes. The clinician specifies the dose fractionation to be used in the radiation treatment of the patient.

Following the process described above, a radiotherapy treatment plan is produced by medical physicists using complex computer algorithms which simulate the effects of a radiation beam passing through the designated area and the radiation dose deposited at any one site. Three or more

Figure 36.2 The planning computer showing a treatment plan and dose-volume histogram.

beams are typically required to produce a homogenous dose for the radiation of pelvic cancers; the use of two beams increases the volume of bowel receiving radiotherapy and risk of radiation enteropathy. However, the use of two opposing anterior-posterior beams is necessary for irradiation of carcinoma of the vulva due to irradiation of inguinal lymph nodes. Modern linear accelerators contain computer-driven multi-leaf collimators which shape the radiation beams to improve conformity to the PTV and to shield the organs at risk. These have replaced the lead blocks previously manually placed in the beam to provide shielding of the organs at risk, thus speeding up the treatment process and reducing the heavy manual work required of therapy radiographers.

The final radiotherapy plan comprises the following information: the number of beams used to optimize conformity to the PTV, beam energies, beam direction, use of wedge angles and multi-leaf collimators to improve PTV conformity, and the dose distribution and percentage dose received by the PTV. A dose-volume histogram is provided to determine the dose being received by the PTV and organs at risk. The final plan is checked and approved by the clinician prior to implementation of the radiotherapy plan (Figure 36.3). Verification checks are performed to validate the treatment plan and to detect for any unforeseen errors prior to starting radiation treatment. A standard dose prescription for carcinoma of the cervix is 45–50 Gy in 25–28 fractions using 1.8 Gy/fraction over 5–5.5 weeks.

The patient is treated in a specially designed room to prevent radiation of personnel outside the room. The patient is positioned on the treatment couch with reference to the tattoo marks (Figure 36.4). Computerized transfer of planning data from the planning computer to the linear accelerator minimizes the risk of human error in transferring data. The radiographers control the linear accelerator from outside the room using a console which is used to start and stop the radiation beam, and to set the duration of treatment and the dose to be delivered. The patient is monitored using cameras in the treatment room, and communication with the patient is possible via a microphone. These safety features are designed to optimize radiation treatment and are subject to frequent quality assurance checks.

Figure 36.3 A computed tomography (CT) slice from a four-field conformal radiotherapy plan to treat a patient with carcinoma of the cervix. The green area represents the clinical target volume (CTV) consisting of the primary tumour plus a margin for microscopic disease and the pelvic nodes. The organs at risk are also drawn on the CT slice: rectum (blue), urinary bladder (purple) and femoral heads (yellow).

Virtual simulation

The planning CT scan images can be reconstructed using computer software to provide a digitally reconstructed radiograph (DRR). Bony landmarks are used for radiotherapy planning with the clinician using the computer software to place the radiation beams on to the DRR. This is akin to conventional radiotherapy. The advantages of virtually simulated radiotherapy planning include: the clinician is able to visualize the pelvic soft tissues by using the CT scan images, thus ensuring the tumour is encompassed within the radiation field; radiotherapy planning is less time-consuming compared with conformal radiotherapy; the clinician can apply multi-leaf collimators at the time of planning to optimize shielding of the organs at risk; and a dose distribution can be provided by the medical physicists to ensure that the PTV is receiving the prescribed dose. The disadvantages of virtually simulated radiotherapy planning are that it is not suitable for producing complex radiotherapy plans, and a dose-volume histogram cannot be provided to determine the dose being received by the organs at risk. Virtually simulated radiotherapy (Figure 36.5) is frequently utilized for pelvic radiotherapy for the reasons outlined above.

Figure 36.5 Anterior (A) and right lateral (B) views of a virtually simulated radiotherapy plan for carcinoma of the cervix. The superior border has been extended superiorly to include the common iliac lymph nodes. The red (A) and green (B) delineated areas denote the planning target volume; the white rectangles represent the multi-leaf collimators used to shield organs at risk which do not need to be irradiated.

Conventional radiotherapy

Conventional external beam radiotherapy uses bony landmarks to define the target volume for pelvic radiotherapy. A simulator film is obtained after the patient is aligned on the simulator couch using orthogonal lasers. Cross wires mounted in the light beam from the simulator define the size of the area to be treated, and anterior-posterior and lateral pelvic X-rays are obtained as permanent records. The clinician is able to identify areas where shielding can be applied to reduce dose to the organs at risk (Figure 36.6). As diagnostic X-rays have poor soft tissue resolution, the clinician must rely on information gathered from clinical examination and radiological investigations to determine the target volume. Studies have reported underdosing of the regional lymph nodes in up to 40% of patients using conventional radiotherapy. However, conventional radiotherapy planning still has a role in centres where access to CT planning software is restricted due to resource implications, in patients unable to fit into a CT scan machine due to gross obesity, and in palliative radiotherapy.

Intensity-modulated radiotherapy

Intensity-modulated radiotherapy (IMRT) is generally regarded as a significant advancement in the development of conformal radiotherapy. A major advantage of IMRT is the ability to generate PTVs which conform to targets which are concave in the plane of the incident beams, which is not possible with standard conformal radiation. This is achieved by using numerous non-coplanar beams of varying intensity

to improve conformity to treatment targets whilst further reducing the dose to selected organs at risk. However, IMRT results in a larger volume of normal tissue receiving low doses of radiation; one of the concerns of IMRT is that, over a period of time, this may result in a higher incidence of secondary malignancies and other unwanted late toxicities.

IMRT may be inverse- or forward-planned. In inverse-planned IMRT, the clinician specifies the dose constraints within the patient and an inverse-planning algorithm computes the beam modulations required to produce the specified dose distribution. A number of planning cycles may be required to produce an 'optimized' dose distribution. Forward-planned IMRT utilizes a limited number of non-coplanar beams of different weighting to deliver a more conformal plan. An additional advantage of IMRT is that it is possible to allocate different dose targets within a single treatment volume by a process called 'simultaneous integrated boost IMRT'.

A number of studies investigating the role of IMRT in cervical and endometrial cancer have been published in the literature. The majority are single-centre retrospective analyses involving fewer than 100 patients.

Whilst the use of IMRT may be promising, there are insufficient long-term data regarding its efficacy and safety in the treatment of gynaecological malignancies. Concerns have been raised regarding the use of IMRT because of the poor visualization of the cervix on CT scans. The use of MRI/CT fusion is currently being explored. IMRT should be regarded as an experimental treatment in gynaecological cancers, and its use should be confined to clinical trials until there are convincing data for its role in these cancers.

Brachytherapy

This entails the delivery of ionizing radiation using sealed sources placed as close to the tumour as possible. The principal advantage of brachytherapy lies in the delivery of a very high dose of radiation to the tumour whilst relatively sparing normal tissues due to a rapid fall-off of dose away from the source according to the principle of the inverse square law. Other advantages over external beam radiation include: the accurate localization of tumour and immobilization of the area being treated reduces set-up errors; and delivery of treatment over a significantly shorter period, thus eliminating the risk of accelerated tumour repopulation associated with protracted courses of radiotherapy. A major disadvantage includes the need to access the tumour, which frequently requires an operative procedure subject to the competency of the brachytherapist. In gynaecological cancers, brachytherapy is commonly used to boost the tumour following external beam radiotherapy, as in cervical cancer. It may be used as the primary treatment for early cancers where surgery is contraindicated (e.g. early cervical and vaginal cancers). Vaginal vault brachytherapy is increasingly used as the sole adjuvant treatment following surgery for endometrial cancer with a good prognosis.

Radionuclides used in gynaecological malignancies

Radium-226 was the first radionuclide used in gynaecological brachytherapy. It has a half-life of 1620 years and decays by alpha emission to its gaseous daughter product, radon-222. There were several disadvantages associated with the use of radium-226, including emission of high-energy photons which required thick shielding and storage of the daughter nuclides for prolonged time periods. Radium-226 has been replaced with more convenient radionuclides such

as caesium-137, cobalt-60 and iridium-192. Other artificially produced radionuclides are likely to become available for brachytherapy use in the future.

Dose rates in brachytherapy

Moderate-dose-rate (MDR) and high-dose-rate (HDR) brachytherapy are commonly used in gynaecological malignancies. Whilst there is no universally accepted definition of dose rate, it is generally accepted that MDR uses dose rates of 1–12 Gy/h whereas HDR refers to dose rates greater than 12 Gy/h. Sufficient data are available to suggest that both are equally effective in achieving tumour control when used in the treatment of gynaecological malignancies. MDR brachytherapy is typically delivered over a period of 12–14 h, and thus requires inpatient treatment in an appropriately designed room. The patient is required to remain flat and immobile during this period to prevent displacement of the applicators. MDR brachytherapy has the radiobiological attraction of allowing treatment to be completed in a short period of time, thus reducing the negative effects of tumour repair and repopulation. Advantages of HDR brachytherapy include shorter treatment times, allowing outpatient-based treatment and the reduced risk of applicator displacement during treatment. However, HDR brachytherapy requires fractionation of treatment to reduce the risk of late tissue toxicity, with three to six fractions being delivered on a weekly basis. This leads to prolongation of the overall treatment time, associated with a theoretical disadvantage of allowing tumour repair and repopulation between treatment fractions. Pulsed-dose-rate (PDR) brachytherapy utilizes HDR treatment to simulate LDR brachytherapy to minimize the radiobiological disadvantages of prolonging overall treatment time. In PDR brachytherapy, pulses of HDR treatment are repeated at short intervals to simulate LDR brachytherapy.

Delivery systems in gynaecological brachytherapy

The manual insertion of radioactive sources into tumours has almost become obsolete and has been superseded by afterloading systems. Afterloading involves the initial placement of non-radioactive applicators within the patient with subsequent insertion of the radioactive material. This has the advantage of significantly reducing the risk of exposing personnel to the radioactive sources. The use of machine (remote) afterloading techniques virtually eliminates the risk of radiation exposure for all personnel, and has become the standard of care in gynaecological brachytherapy.

Intracavitary brachytherapy

This technique is routinely used for the radical treatment of cervical cancer where hysterectomy has not been performed, and occasionally in patients with inoperable endometrial cancer. The procedure is carried out under general anaesthesia unless contraindicated, in which case spinal anaesthesia provides a suitable alternative. The patient is examined to assess tumour size and parametrial involvement, and a urinary catheter is inserted. Following cervical dilatation, a sound is used to assess the uterine length. The width of the vaginal vault is estimated to guide the applicator sizes required. The intrauterine tube is inserted first, followed by the vaginal applicators. A rectal retractor may also be inserted to push the anterior rectal wall further away from the applicators; alternatively, a gauze pack may be used to achieve this purpose and also to secure the applicators in place. A simulator film is taken with the applicators in place once the patient is awake, which is then transferred on to a planning computer to allow dosimetry calculations to be performed. The patient is treated in an appropriately shielded room using a remote afterloading system (Figure 36.7). The patient is monitored via a camera inside the treatment room, and a microphone can be used to communicate with the patient. Once treatment is completed, the applicator and gauze packing are removed and the patient is discharged home.

A number of applicator systems are available for intracavitary brachytherapy, all of which are based around the principle of delivering a high radiation dose to the cervix, parametrium and upper vagina. Two main types of applicator are available (Figure 36.8a,b,c).

- A central intrauterine tube and lateral vaginal sources (ovoid). Several variations on this theme are available for use.
- A central tube and ring applicator. This technique is considered to allow greater individualization of dose distribution. It is a variation of the intrauterine and ovoids mentioned above.
- A single line source, which is advocated by some brachytherapists. It is useful for treatment where the cervical carcinoma is extending down into the vagina.

The Manchester system was developed to calculate and describe the dose distribution for intracavitary brachytherapy. The system specified activity loadings for the intrauterine tube and each ovoid to give a dose defined to a defined reference point, called 'Point A'. This is defined as being 2 cm lateral to the centre of the uterine canal and 2 cm superior to the mucous membrane of the lateral fornix along the line of the uterine canal. An additional point (Point B)

Figure 36.7 A remote afterloading high-dose brachytherapy machine. Once the applicators are inserted and a radiotherapy plan is produced, the applicators are attached to the machine using catheters. The patient is treated in the room in isolation to allow protection of staff from the ionizing radiation.

placed 3 cm lateral to Point A is used to calculate the dose received by the pelvic side wall.

Conventionally, a total dose of 75–85 Gy is delivered to Point A. Following external beam radiotherapy with a dose of 45–50 Gy in 25–28 fractions, a dose of 25–27 Gy is delivered to Point A using MDR brachytherapy. A number of recommendations exist for the total dose and number of fractions used for HDR brachytherapy. The most commonly used dose fractionation is 21 Gy in three fractions using 7 Gy per fraction.

Vaginal vault brachytherapy

Following hysterectomy, women with cervical or endometrial cancer with pathological features suggestive of a high risk of relapse are often recommended to have adjuvant radiotherapy, including vaginal vault brachytherapy where appropriate. Vaginal vault brachytherapy is increasingly being used as the sole adjuvant treatment for endometrial cancer in women with intermediate–high risk of pelvic relapse. A number of vaginal applicators are available for use, including vaginal cylinders (Figure 36.8D) of varying sizes, vaginal ovoids or individualized vaginal moulds. Applicator insertion may be carried out on the ward or in the brachytherapy suite, although some brachytherapists prefer the procedure to be carried out in theatre under general anaesthesia.

Following insertion of the applicators, patients undergo the same planning process as for intracavitary brachytherapy. Following external beam radiotherapy (45 Gy in 25 fractions), a dose of 15 Gy is prescribed to 5 mm if using MDR brachytherapy. If using HDR brachytherapy, 12 Gy in two or three fractions may be prescribed.

Interstitial brachytherapy

Interstitial brachytherapy is used for the treatment of tumours of the vagina and vulva, either as primary treatment for small tumours or to boost the primary tumour following external

Figure 36.8 Different types of applicators available for intracavitary brachytherapy. (A) Intrauterine tube and two ovoids, which is used as the standard applicator system for delivering intrauterine brachytherapy, although some centres use the intrauterine tube and ring applicator shown in (B). Other brachytherapists advocate the use of a single line source as shown in (C). An example of a vaginal cylinder applicator used for vaginal vault brachytherapy is also shown (D).

beam radiotherapy. It can also be used for palliating symptoms for locally recurrent or metastatic cancers of the vagina and vulva. Either LDR iridium wire interstitial implants or HDR afterloading implant techniques can be used for perineal implants using some form of perineal template (Figure 36.9). Perineal implants are performed under general or spinal anaesthesia. Computer-based planning allows for more accurate visualization of the tumour in relation to the implant (Figure 36.10).

Image-guided adaptive brachytherapy

Simulator-based dosimetry for intracavitary brachytherapy relies on doses to points (e.g. Point A) rather than to volumes. For advanced cervical tumours, prescribing to Point A may lead to tumour underdosage as a proportion of the tumour may lie outside the high-dose envelope. Image-guided adaptive brachytherapy uses CT and/or MRI imaging to allow visualization of the tumour in relation to the applicator and the organs at risk at the time of brachytherapy to enable dose adaptation to the target whilst improving the sparing of normal tissues (Figure 36.11). The possibility of fusing FDG-PET images with planning CT software provides another potential avenue for the use of adaptive brachytherapy to improve tumour control.

Image-guided adaptive brachytherapy is a relatively new concept for the treatment of cervical cancer, and is only available in a few centres. Some of the challenges to the widespread adaptation of this technique include: the availability of CT- and MRI-compatible applicators, the availability of software to define applicator geometry for CT and MRI, coregistration of pelvic CT and MRI images, and a limited number of published clinical results. Image-based adaptive brachytherapy continues to generate significant interest, with the potential of improving tumour control and significantly reducing treatment-related morbidity.

Radiation morbidity

Treatment-related morbidity is the dose-limiting factor when utilizing radiotherapy for the curative treatment of any cancer, and has potentially important physical and psycho-social consequences for the patient. The risk of unwanted radiation effects is determined by the interaction of tumour- and patient-related factors. Unwanted radiation effects are divided into early effects, arbitrarily defined as those occurring within 90 days of starting treatment, and late effects, defined as those occurring more than 90 days after starting treatment. In pelvic radiotherapy, the small bowel, rectum and bladder are the main organs at risk. The kidneys and spinal cord are the vital organs at risk when para-aortic lymph node irradiation is required. Table 36.1 summarizes the early and potential late effects associated with pelvic radiation.

Conclusion

Radiotherapy continues to play a central role in the treatment of gynaecological malignancies. Technological advances are allowing increasingly sophisticated ways of planning and delivering radiation treatment in this group of patients. This is accompanied by ongoing research in ways to improve tumour control whilst minimizing the unwanted effects of radiotherapy.

Chemotherapy

Cytotoxic chemotherapy as a primary treatment modality cures less than 5% of all malignancies. It is the definitive mode of treatment in gestational trophoblastic tumours and germ cell tumours of the ovary. Chemotherapy is often used in conjunction with other treatment modalities such as surgery and radiotherapy in the treatment of gynaecological malignancies, either in an attempt to effect cure (radical), or to palliate symptoms and prolong survival in patients with

Figure 36.11 (A, B) Image-guided brachytherapy showing the treatment of a patient with cervical carcinoma with right parametrial involvement using interstitial brachytherapy. Treatment is performed using standard intracavitary treatment and interstitial brachytherapy to boost the right parametrium, thus allowing greater conformity of treatment using image-guided brachytherapy.

advanced or metastatic disease (palliative chemotherapy). Adjuvant chemotherapy is utilized where disease is known or suspected to be present after surgery, with the intent of prolonging disease-free and overall survival (e.g. in ovarian or endometrial carcinoma). There is increasing interest in the role for neoadjuvant chemotherapy to reduce the burden of tumour prior to definitive surgery in advanced ovarian carcinoma. The use of concurrent chemoradiation is well established in the radical treatment of cervical carcinoma. It is also used for the radical treatment of selected cases of vulval cancer. The use of chemotherapy in patients with metastatic incurable cancers poses unique challenges; whilst chemotherapy may extend survival, treatment is often associated with unwanted side-effects which can negatively impact on the patient's quality of life. On the other hand,

Table 36.1 Early and late unwanted radiation effects

Organ	Early effect	Late effect
Skin	Erythema, desquamation	Telangiectasia, fibrosis
Small bowel, sigmoid and rectum	Radiation colitis or proctitis	Radiation proctitis, diarrhoea, bowel stenosis, fistulae
Bladder	Radiation cystitis	Radiation cystitis, fistulae
Hip joints and pelvic bones		Osteoradionecrosis, insufficiency fractures
Ovaries		Infertility, menopause
Vagina	Mucositis	Vaginal stenosis, fistulae
Lymph nodes		Lymphoedema
Spinal cord		Radiation myelopathy
Kidneys		Renal failure, hydronephrosis
General		Secondary cancers

response to palliative chemotherapy can lead to improvement in the patient's symptoms with subsequent improvement in quality of life. Prior to embarking on a course of palliative chemotherapy, several factors must be taken into account, including performance status, previous treatments, response rates to chemotherapy, utility of other treatments to alleviate symptoms and, ultimately, the patient's wishes and expectations.

Drug discovery and clinical trials

Historically, the process of drug discovery relied on highly empirical approaches based on testing randomly selected compounds against rapidly proliferating murine leukaemic cells. This has been replaced by rational drug design based on the expanding knowledge of the molecular mechanisms of cancer, and the use of automated in-vitro screens using panels of human tumour cell lines, some chosen for their resistance to existing agents.

Of the hundreds of thousands of chemical and biological agents tested in laboratories, only a small number find their way into routine clinical use. Before any new agent can be tested on humans, it undergoes preclinical studies to assess both its efficacy and toxicity in animal models. A promising agent is then studied in phase I studies to determine the appropriate dose of the drug to be used in its subsequent development. Phase I trials are designed to define a drug's dose-limiting toxicities and the maximum tolerated dose. Pharmacokinetic studies form an integral part of phase I studies. Phase II studies are designed to assess the activity of a particular drug in different tumour types, measured as response rates. A drug demonstrating 'activity' in a particular tumour type is subsequently tested in phase III trials to further define its effectiveness and clinical utility.

Pharmacology

For a given chemotherapeutic agent to be effective, several features must be present, including: the drug must reach the

cancer cells, sufficiently toxic amounts of the drug or its metabolites must enter the cell and remain there for an adequate period of time, and the cancer cells must be sensitive to the drug or its metabolites and must not overcome its effects by developing resistance to treatment. Pharmacology involves the study of drug pharmacokinetics and pharmacodynamics.

Pharmacokinetics is the study of processes that determine the concentration of the drug and its metabolites within the body (i.e. absorption, distribution, metabolism and excretion). Pharmacodynamics is the study of the relationship between drug concentration and effect. In oncological treatment, this therapeutic index may be quite narrow in that the dose required for therapeutic effect may be close to that which could cause severe side-effects. In most studies, drug plasma concentration is taken as the conventional measure for drug concentration at the site of action. The shape of the concentration–time curve is a predictor of effect and is defined by the pharmacokinetics.

Drugs can only be taken orally if they are well absorbed from the alimentary tract. Parenteral administration — intravenous, intramuscular or intra-arterial — is the optimal route for most chemotherapy agents as oral administration can result in poor absorption and uncertain bioavailability, particularly because of first-pass metabolism through the liver. However, after a bolus injection, redistribution will account for the initial fall in plasma concentration and is controlled by both redistribution and elimination. The latter is the sum of metabolism and excretion, although some drugs are excreted unchanged and others are metabolized and excreted. Excretion of drugs is a complicated process but usually involves both the liver and kidneys.

Another factor which determines drug concentration is protein binding. A number of cytotoxic drugs (e.g. etoposide) are heavily protein bound, and small reductions in binding could lead to a significant increase in drug concentration. Changes in protein binding may be caused by other drugs competing for binding sites. Redistribution of a drug increases clearance and factors such as cachexia may reduce this, as can hepatic and renal dysfunction. It can therefore be seen that knowledge of a drug's pharmacokinetics and pharmacodynamics is essential in order to predict and avoid either potential under- or overdosing.

In a clinical setting, factors such as serum albumin, liver function tests, creatinine, patient's age and performance status, and previous exposure to chemotherapy can guide the clinician in estimating the dose of chemotherapy to be used.

Routes of administration

Systemic chemotherapy

With intravenous administration, drugs are normally given at intervals of 1–4 weeks which permits recovery of bone marrow function between pulses of treatment. Although some cancer cells will also recover, there is a net loss of cancer cells in every cycle.

Intraperitoneal chemotherapy

The use of the intraperitoneal route to deliver chemotherapy in ovarian cancer has a long history. The attraction of such an approach is that high concentrations of drugs can be delivered into the peritoneal cavity which acts as a reservoir,

releasing the drugs slowly into the systemic circulation. This results in very high and prolonged local concentration of the drug. However, absorption of cytotoxic drugs directly into tumour nodules is limited as penetration will only be three to six cells deep. Some agents are unsuitable because they cause a severe local chemical peritonitis. Cisplatin can be given by this route, but if the dose is too high, systemic complications ensue. Three randomized phase III trials have now shown that intraperitoneal delivery of a cisplatin-based regimen results in a 20–25% relative reduction in mortality for patients with small-volume residual advanced ovarian cancer. A variety of strategies are being investigated to improve the toxicity profile of platinum-based intraperitoneal chemotherapy.

Dose calculation

To give equivalent dosages to patients, the dose of chemotherapy drugs is based on an estimate of the patient's surface area (m^2), calculated from height and weight. Use of granulocyte-stimulating colony factors or dose modification may be required where bone marrow toxicity is encountered in order to prevent severe neutropenia and risk of infection. With renal or hepatic impairment, doses of drugs excreted by the kidneys or metabolized by the liver are reduced. Carboplatin dosage is often based upon a measurement of renal function, rather than surface area. This is called the 'Calvert formula' and allows the clinician to calculate a dose which will provide a specified area under the concentration–time curve.

Duration of therapy

The optimum duration of chemotherapy remains unknown. The duration of chemotherapy is determined by a number of factors including the indication for treatment, tumour response to chemotherapy, and patient tolerance to side-effects of chemotherapy. In practice, chemotherapy is usually given for 12–24 weeks, with prolongation of treatment being associated with a greater risk of toxicity.

Rarely, where tumours release a specific tumour marker such as β -human chorionic gonadotrophin in trophoblastic disease, marker measurements allow the treatment period to be defined more accurately for individual patients. Sufficiently sensitive and specific tumour markers are not yet developed for the common gynaecological tumours.

Drug resistance

The development of resistance to chemotherapeutic drugs by neoplastic cells remains one of the major obstacles in attempts to cure cancers with chemotherapy alone. Whilst some cells are inherently resistant, others adapt by using various detoxification pathways to acquire resistance. One common process that may cause resistance to virtually all chemotherapy agents is referred to as suppression or inactivation of cell-damage-induced apoptosis or loss of the apoptotic pathway, which results from inactivation of the *p53* tumour suppressor gene.

Other mechanisms of drug resistance include: overexpression of the Bcl-2 protein; overexpression of the multi-drug resistance (*MDR-1*) gene enhancing production of the transmembrane protein P-170 which functions as a pump capable of ejecting cytotoxic agents from the cell; alteration of topoisomerase enzyme activity; and increased levels of

intracellular concentrations of glutathione and glutathione S-transferase isoenzymes.

Principles of combination therapy

Single-agent chemotherapy rarely cures human cancers, and combination chemotherapy was developed to provide maximal remission in most tumour types. The guiding principles of combination chemotherapy include:

- each agent must have single-agent activity against the tumour under study;
- drugs acting at different intracellular targets can be combined to give a synergistic effect;
- drugs with different toxicities can be combined to avoid the cumulative toxic effects of each individual drug;
- drugs must be administered as close as possible to their optimal dose and at a minimal interval, taking into account the toxicity of therapy; and
- the ability of tumour cells to develop resistance to cytotoxic therapy is reduced.

The case for combination chemotherapy in gynaecological cancers has not been proven completely in first-line treatment of ovarian cancer. Similar controversies also exist in advanced or metastatic cervical cancer, where potentially higher response rates have been associated with increased toxicity, possibly negating any therapeutic gain.

An alternative method of preventing the development of drug resistance is to give different drugs in turn. This also allows for a shorter treatment time, as severely myelotoxic drugs can be alternated with those which have no effect on the bone marrow. This approach has been effective in treating germ cell tumours and trophoblastic disease, but not epithelial tumours.

Classification

The most common classification of cytotoxic drugs is based on their mechanisms of action. Drugs are divided into alkylating agents, antimetabolites, vinca alkaloids, antibiotics, topoisomerase inhibitors, tubulin-binding agents and others. Table 36.2 summarizes the mechanism of action and toxicity of some of the chemotherapy agents mentioned below.

Alkylating agents

These drugs cross-link DNA strands and intracellular proteins by forming covalent bonds between highly reactive alkylating groups and nitrogen groups on the DNA helix. This either prevents division of the helix at mitosis or transcription of RNA, and results in imperfect division and cell death.

The most frequently used alkylating agents in gynaecological cancers are carboplatin and cisplatin. Previously used agents include cyclophosphamide, ifosfamide, chlorambucil, melphalan and treosulfan. Some alkylating agents may be taken orally.

Both cisplatin and carboplatin contain platinum. They act in a similar way to alkylating agents, forming DNA adducts. Both are given intravenously but, because of its potential nephrotoxicity and associated hypomagnesaemia and hypokalaemia, cisplatin requires a forced diuresis and elec-

Table 36.2 Chemotherapeutic agents used in gynaecological cancers, mechanisms of action and toxicities

Drug	Mechanism of action	Toxicity	Clearance
5-Fluorouracil	Antimetabolite, inhibits thymidine synthesis	Bone marrow suppression, mucositis, nausea, vomiting, diarrhoea, PPE	Hepatic, renal
Bleomycin	Antitumour antibiotic, DNA strand breakage	Anorexia, skin pigmentation and peeling, fever, rigors, interstitial pneumonitis, pulmonary fibrosis	Renal
Carboplatin	DNA cross-link, covalent adduct	Thrombocytopenia, neutropenia, nausea, vomiting	Renal
Cisplatin	DNA cross-link, covalent adduct	Neutropenia, thrombocytopenia, nausea, vomiting, peripheral neuropathy, ototoxicity, autonomic neuropathy, renal impairment, hypokalaemia, hypomagnesaemia	Renal
Docetaxel	Promotes tubulin synthesis and inhibits microtubule depolymerization, interferes with cell division	Bone marrow suppression, alopecia, nausea, vomiting, mucositis, peripheral neuropathy, fluid retention, arthralgia, myalgia, capillary leak syndrome, allergic reactions	Hepatic
Epirubicin	Topoisomerase II inhibitor	Bone marrow suppression, alopecia, vesicant, nausea, vomiting, cardiomyopathy	Hepatic
Etoposide	Topoisomerase II inhibitor	Bone marrow suppression, alopecia	Renal
Ifosfamide	Alkylating agent	Bone marrow suppression, alopecia, nausea, vomiting, haemorrhagic cystitis, encephalopathy	Renal
Liposomal doxorubicin	Topoisomerase II inhibitor	Bone marrow suppression, alopecia, PPE, cardiomyopathy	Hepatic
Methotrexate	Antifolate antimetabolite	Bone marrow toxicity, mucositis, exfoliative dermatitis, renal impairment	Renal
Paclitaxel	Tubulin synthesis deregulation	Bone marrow toxicity, nausea, vomiting, alopecia, allergic reactions, peripheral neuropathy, autonomic neuropathy	Hepatic
Topotecan	Topoisomerase I inhibitor	Bone marrow toxicity, alopecia, nausea, vomiting	Renal

PPE, palmar–plantar erythrodysesthesia.

trolyte replacement. It is also associated with severe nausea and vomiting which require potent antiemetic therapy. Peripheral neuropathy and ototoxicity are recognized side-effects which can be disabling and are usually dose related. Cisplatin has little myelotoxicity except for anaemia.

Carboplatin is less frequently associated with nephrotoxicity or neurotoxicity, and is also less emetogenic. It may be given as a short outpatient infusion. The most common side-effect of carboplatin is bone marrow suppression, with thrombocytopenia being a particular problem, especially in the context of impaired renal function. There is increasing recognition that platinum-associated hypersensitivity reactions are seen when carboplatin is used in the second-line setting. Data suggest that more than 10% of patients treated with carboplatin will experience this reaction, which can vary from a mild rash to hypotensive shock. A variety of desensitization schedules have been devised; however, patients can be challenged with cisplatin if it is felt to be too dangerous to continue with carboplatin.

Ifosfamide is an alkylating agent which is activated by hepatic microsomal enzymes. Bone marrow suppression is the dose-limiting toxicity and it also causes marked alopecia. It is excreted in the urine in the form of active metabolites, which can cause severe chemical cystitis when given in high doses unless mesna (sodium 2-mercaptoethanesulphonate) is administered at the same time to protect the bladder mucosa. In addition, ifosfamide may cause a fatal encephalopathy and must only be given after reference to a treatment nomogram.

Antimetabolites

These compounds closely resemble metabolites essential for the synthesis of nucleic acids and proteins. They are incorporated into natural metabolic pathways and enzyme systems, and disrupt the cellular mechanism. Each antimetabolite acts at different sites in the pathway of nucleic acid synthesis. These drugs include 5-fluorouracil (5-FU), methotrexate, capecitabine and gemcitabine.

Methotrexate

Methotrexate is a folic acid antagonist. It inhibits the enzyme dihydrofolate reductase, which reduces dihydrofolate to tetrahydrofolate; the precursor of coenzymes essential for the formation of purines and pyrimidines (nitrogen bases of DNA). These effects are bypassed by giving folinic acid. Folinic acid rescue is given from approximately 12 h after the methotrexate dose to all patients receiving 100 mg or more. The most common complication with methotrexate is oral ulceration. As it is excreted in urine, the dose must be reduced in women with renal impairment or with large fluid collections such as ascites which delays excretion.

5-fluorouracil

5-FU is a pyrimidine analogue which blocks thymidine synthesis and inhibits the incorporation of uracil into DNA. Myelosuppression and mucositis are the most common toxic effects. Patients with a rare inherited deficiency of the enzyme dihydropyrimidine dehydrogenase (DPD) can

develop unexpectedly severe toxicity, including 5-FU-induced colitis. Capecitabine is an oral prodrug of 5-FU which is metabolized by intracellular enzymes into the active metabolite. Palmar-plantar erythrodysesthesia (PPE) is a commonly recognized side-effect.

Gemcitabine

Gemcitabine is converted to gemcitabine diphosphate, which inhibits the activity of ribonucleotide reductase and production of intracellular nucleotides. It competes with cytarabine, thus inhibiting DNA synthesis. Common toxicities include bone marrow suppression, nausea and vomiting.

Vinca alkaloids

Vinca alkaloids act during the metaphase of mitosis, probably through toxicity to the microtubules of the mitotic spindle. Peripheral and autonomic neuropathy are particular problems with vinca alkaloids, particularly vincristine. In addition, they are very irritant and are best injected into a fast-flowing drip. Vincristine is one of the very few chemotherapeutic drugs that is not myelotoxic.

Topoisomerase inhibitors

There are two different types of topoisomerase inhibitors. Both interfere with the transformation of DNA which is required for mitosis. Topoisomerase-1 inhibitors include topotecan and irinotecan, and topoisomerase-2 inhibitors include the epipodophyllotoxins (e.g. etoposide) and the anthracyclines [e.g. doxorubicin (including liposomal doxorubicin) and epirubicin].

Topotecan

Topotecan inhibits DNA replication by inhibiting the enzyme topoisomerase-1. Bone marrow suppression, particularly neutropenia, is the dose-limiting toxicity. Other side-effects include nausea, vomiting, stomatitis and asthenia. It is not recommended in women with renal or significant hepatic impairment.

Etoposide

Etoposide is a semisynthetic derivative of podophyllotoxin that blocks the cell cycle in G1 as well as DNA replication in the S phase. It prevents topoisomerase-2 from completing recombination repair. Cell cycle progression ceases and DNA strands break up, leading to cell death. Etoposide can cause telomeric shortening which accounts for the associated increased risk of leukaemia.

Anthracyclines

Doxorubicin is an antibiotic with antitumour activity that forms a stable irreversible complex by binding to DNA and topoisomerase enzymes, resulting in DNA damage that interferes with replication and transcription. It also interacts with cell membranes altering their function and generating hydroxy radicals which are highly destructive to cells. It causes marked alopecia, is myelosuppressive and should always be given as a fast-running infusion as it is very irritant and will cause a necrotic ulcer if it extravasates. Cardiomyopathy results from high cumulative doses unless the total dose is limited to 450 mg/m². The dose should be modified in the presence of hyperbilirubinaemia.

Pegylated liposomal doxorubicin (PLDH) consists of doxorubicin encapsulated in liposomes that have been pegylated (i.e. have surface-bound methoxy-poly-ethylene-glycol). This pegylation protects the liposomes from destruction in the circulation, and enhances the drug concentration and localization in tumour cells with a consequent increase in therapeutic efficacy and reduction in toxicity. Patients may exhibit infusion reactions which can be prevented with antihistamine and steroid premedication, and can develop PPE, stomatitis and haematological toxicity. PPE usually results in a painful macular rash affecting the hands, feet and skin folds (e.g. groin and axillae). These cutaneous side-effects are often self-limiting but occasionally result in significant toxicity, including crusting, ulceration and necrosis, which may require dose modification or even cessation of treatment. Patients receiving PLDH may need monitoring for cardiac toxicity.

Bleomycin

Bleomycin is another antitumour antibiotic which causes DNA strand breakage, thus interfering with DNA replication. It is not myelotoxic; however, the most important side-effect is pulmonary fibrosis, which is dose related and not often seen at a cumulative dose below 300 mg/m².

Taxanes

The taxanes include paclitaxel (Taxol) and docetaxel. They work by promoting microtubule assembly and stabilizing tubulin polymers, which results in the formation of non-functional microtubules, thus inhibiting mitosis. Taxol is active in ovarian and breast cancers as well as in many other tumours. Hypersensitivity reactions are less commonly experienced with a premedication cocktail of antihistamines, H₂ antagonists and steroids. The vast majority of patients develop total alopecia. Other side-effects include nausea, vomiting, peripheral neuropathy and myalgia. It is now usually given as a 3-h infusion in a non-PVC system by the manufacturers. When combined with a platinum agent, Taxol should be administered first to reduce toxicity and increase synergism. The reverse is the case for combination with doxorubicin.

Docetaxel has a slightly different side-effect profile compared with Taxol, with a reduced incidence and severity of peripheral neuropathy but a higher incidence of bone marrow suppression.

Chemotherapy-related toxicity

Tissues affected by toxic effects include the bone marrow, injection site, skin, hair, mucosa, gastrointestinal tract, reproductive system, heart, lungs, liver, renal system and nervous system. Knowledge of these toxic effects is essential for the safe management of chemotherapy. The most common toxicities for each of the commonly used drugs are shown in Table 36.2. Patients with poor performance, multiple comorbidities and heavily pretreated patients are less likely to tolerate chemotherapy.

Bone marrow suppression

This is a side-effect of almost all of the chemotherapy agents because of their action on bone marrow stem cells, the

exceptions being vincristine and bleomycin. The blood count must be checked regularly and before each course of treatment. Neutropenia can result in infections not only from infective organisms such as *Staphylococcus aureus*, but also from opportunistic organisms which normally cause no problems in healthy individuals. Fungal infections also occur. Infections need to be treated aggressively as they can be life-threatening. Granulocyte colony-stimulating factors increase the tolerance of bone marrow to chemotherapy, reducing the incidence of secondary infections. Thrombocytopenia and anaemia may also occur and may need correction.

Alimentary tract toxicity

Nausea and vomiting are common side-effects of chemotherapy but can be well controlled with the armamentarium of antiemetics currently available to oncologists. Mucositis can result in patient discomfort, but is usually manageable with appropriate advice and appropriate treatment. Diarrhoea is a commonly encountered side-effect of 5-FU and its prodrug capecitabine, but it is usually self-limiting and can be easily managed with loperamide or codeine phosphate. Patients with DPD deficiency can develop fulminant diarrhoea due to 5-FU-induced colitis.

Alopecia

Alopecia is a common problem encountered with some agents but is seldom permanent.

Reproductive system

Chemotherapy may cause permanent infertility, but many young women successfully treated for germ cell tumours have had normal pregnancies. Cytotoxic drugs during pregnancy, particularly in the first trimester, can result in spontaneous abortion or congenital abnormalities. Young women undergoing treatment for gynaecological cancers are often rendered postmenopausal and may require hormone replacement therapy to reduce the long-term effects of early menopause. Other associated effects, such as loss of libido and vaginal dryness, can have a significant impact on the patient's quality of life.

Heart

Doxorubicin can cause cardiomyopathy which can result in heart failure. The risk is dose related. If the total dose is kept below 450 mg/m² and it is not used in patients with impaired cardiac function, cardiotoxicity is rarely seen.

Lungs

Bleomycin can cause pulmonary fibrosis and severe respiratory distress. Therefore, chest X-rays and respiratory function tests are essential before treatment. Anaesthesia after bleomycin also carries an increased risk, and anaesthetists need to be aware that the drug has been given in the past.

Kidneys

Nephrotoxicity is a serious complication of cisplatin and resulted in fatalities until forced diuresis was found to reduce

renal damage. The toxicity is dose related. To avoid serious renal damage, serum creatinine should be measured before every course. If it increases by more than 25% over the pre-treatment value, a creatinine or ethylenediaminetetra-acetic acid clearance should be performed. If the clearance is less than 50 ml/min, the dose should be reduced by 50%. If the clearance is less than 40 ml/min, cisplatin should be discontinued.

Carboplatin has largely replaced cisplatin in the treatment of ovarian cancer as it is less nephrotoxic.

Nervous system

Cisplatin causes a dose-dependent peripheral neuropathy and high-tone deafness. The taxanes, paclitaxel in particular, are associated with peripheral neuropathy which can lead to loss of sensation and muscle weakness. Autonomic neuropathy is also a recognized side-effect of the taxanes. Vincristine can also result in peripheral and autonomic neuropathy. Treatment with ifosfamide can result in encephalopathy, especially in patients with a low serum albumin concentration.

Skin toxicity

Extravasation of some intravenously administered chemotherapeutic agents (e.g. vincristine and doxorubicin) can give rise to phlebitis or thrombosis which can be avoided by giving bolus injections into a free-running infusion. If such drugs leak out into the subcutaneous tissues, they can result in marked morbidity, including large painful ulcers and loss of function. 5-FU, capecitabine and liposomal doxorubicin are associated with PPE, which is usually self-limiting and resolves on cessation of treatment. The taxanes are associated with nail toxicity manifesting as hyperpigmentation, cracking and loss of nails.

Allergic reactions

This can be encountered with any chemotherapeutic agent, usually in the context of rechallenging patients with the same agent, but is also infrequently seen with the first cycle of treatment. Reactions can vary from mild symptoms to anaphylactic reactions requiring inpatient treatment including cardiopulmonary resuscitation.

Hormones

Tamoxifen is a selective oestrogen receptor modulator which has shown activity in the treatment of platinum-resistant ovarian cancer. Histological confirmation of overexpression of the oestrogen- or progesterone-receptor status must be obtained prior to commencing patients on tamoxifen. Common side-effects include hot flushes, night sweats and an increased risk of thromboembolic disease. It also increases the risk of endometrial cancer; however, most women with ovarian carcinoma undergo hysterectomy as part of routine surgical management.

Progestins such as medroxyprogesterone acetate are used in the palliative treatment of hormone-positive endometrial cancer. There is little evidence that doses higher than 200 mg twice daily are more effective. Although widely regarded as free of side-effects and toxicity, many patients do complain

of fluid retention and there is some concern that prolonged use may increase the risk of cardiovascular disease. Glucocorticoids are often useful as antiemetics and in terminal care.

Conclusion

Chemotherapy plays an important part in the management of ovarian cancer, and its use can largely explain the improved prognosis for this disease which has been seen over the last decade in the West. The rare trophoblastic and germ cell tumours are now cured by these drugs in the vast majority of patients. In the treatment of solid tumours, it

may be used in combinations with surgery and radiotherapy, and in cervical cancer, there is evidence that concurrent chemoradiation improves outcome compared with radiotherapy alone.

The dramatic increase in the number of potential drugs available as well as those in the developmental pipeline means that toxicity has been improved, and quality of life is an important goal. Indeed, no new agent is likely to be developed without an assessment of quality of life.

The most important contribution from chemotherapy is likely to be improved quality and duration of survival. This has already been achieved in ovarian cancer and there are reasons for optimism over the forthcoming years.

KEY POINTS

1. Most radiotherapy is delivered in the form of electromagnetic radiation using either high-energy X-rays generated by linear accelerators or radioactive isotopes.
2. Radiotherapy is usually given over many fractions to exploit the radiobiological differences between tumour clonogens and normal tissues.
3. Cisplatin-based chemoradiation is the generally accepted standard of care for the radical treatment of cervical carcinoma.
4. Technological advances are improving the accuracy with which radiotherapy is delivered, and also lead to reduced exposure of staff to ionizing radiation.
5. A major advantage of brachytherapy is the principle of the inverse square law which permits the delivery of high doses of radiation with relative sparing of normal tissues.
6. Late effects of radiotherapy including the effects on the gastrointestinal tract, bladder and bone marrow can have a significant impact on patients' quality of life.
7. Chemotherapy as a primary treatment modality cures approximately 5% of all cancers, and is the definitive mode of treatment for gestational trophoblastic tumours and ovarian germ cell tumours.
8. Chemotherapy is often used with other treatment modalities such as surgery and radiotherapy for the radical treatment of gynaecological malignancies.
9. All chemotherapeutic agents are associated with toxicity and can sometimes have an adverse effect on patients' quality of life, which is particularly important in the palliative setting.
10. All chemotherapeutic agents undergo stringent clinical trials prior to being approved for general clinical use.
11. Knowledge of pharmacokinetics and pharmacodynamics is vital to ensure that patients are treated effectively and safely.
12. Resistance to chemotherapeutic agents is one of the major unsurpassed hurdles which continues to pose significant challenges for the role of chemotherapy in curing cancers.

Introduction

Ovarian cancer is the fourth most common cause of cancer death in women, with a worldwide incidence of 200,000 cases causing 115,000 deaths per year. As described elsewhere, the current standard of care for women with stage IC (and stage IB with adverse histological features) to stage III disease is surgery followed by adjuvant chemotherapy. Further lines of treatment can be given when patients relapse but cure is not possible. Ovarian cancer is considered to be a chemosensitive disease, with nearly 75% of patients initially responding to platinum-based treatment. The choice of agent upon relapse depends on the timing of relapse; if this is over 6 months from previous platinum administration, this can be repeated either as a single agent or as part of a combination regimen, as patients are still considered to be platinum sensitive. If relapse occurs within 6 months of previous platinum administration, non-platinum drugs such as pegylated liposomal doxorubicin are used. There is an increased understanding of the complicated biological pathways involved in the development of gynaecological cancers, their subsequent metastagenesis and the mechanisms involved in chemoresistance. Many clinical studies are underway investigating the use of novel agents in patients with gynaecological malignancies, either alone, concurrently with chemotherapy or sequentially, in an attempt to improve response rates/durations and thereby survival. This chapter will outline several of the new classes of novel agents which are at various stages of development, detail their putative mechanisms of action and their potential indications, and

include brief summaries of their toxicity profiles from studies to date. Many of the phase II studies of new agents include patients in the platinum-refractory group, whose tumours are intrinsically resistant to chemotherapy and radiotherapy, and who therefore have low rates of response to conventional treatment.

Vascular Endothelial Growth Factor and Angiogenesis Inhibition

Angiogenesis or neovascularization is a normal physiological process involving the remodelling of vasculature and formation of new blood vessels. Angiogenesis plays a vital role in tumour formation and metastasis because both primary lesions and metastatic tumours must develop a new vascular supply in order to survive (Folkman 1971, 1990). Early initiation of angiogenesis is essential for cancer survival, and occurs when stimulatory factors overcome inhibitory factors, promoting the formation of new blood vessels (Bergers and Benjamin 2003).

Research investigating the molecular basis of angiogenesis has identified multiple pathways that contribute to tumour angiogenesis. These include vascular endothelial growth factor (VEGF), fibroblast growth factor and platelet-derived growth factor (PDGF). Based on the central role of VEGF in tumour angiogenesis and growth, this has emerged as the most promising therapeutic target for angiogenesis inhibition. The VEGF molecule interacts with cell surface VEGF receptors (VEGFRs) that initiate signalling through

downstream pathways to promote growth and differentiation of vascular endothelial cells and formation of new blood vessels.

The biological roles of VEGF predict that its expression should be related to clinical outcome in cancer patients. Indeed, VEGF expression has been correlated with both disease-free survival and overall survival (OS) in a variety of gynaecological cancers. VEGF expression has been evaluated in women with ovarian carcinoma in several studies, which collectively provide consistent evidence that higher VEGF levels are associated with aggressive clinical behaviour in ovarian carcinoma. Kassim et al (2004) found some degree of VEGF expression in all ovarian cancer specimens examined, and the level of VEGF expression was significantly higher in tumour specimens compared with benign ovarian tissue. In addition, rising titres of VEGF from tumour specimens correlated with increasing stage and decreased survival. This relationship seems to be independent of important clinical and pathological prognostic factors. Furthermore, in women with ovarian cancer, high serum levels of VEGF are an independent risk factor for ascites, advanced-stage disease, undifferentiated histology, more metastases and decreased survival (Cooper et al 2002, Li et al 2004).

There are limited data regarding VEGF expression in endometrial cancer specimens. Holland et al (2003) documented VEGF expression in 100% of the endometrial cancer specimens examined. In addition, they found no expression of VEGF in benign endometrial tissue. The functional significance of the VEGF/VEGFR axis in endometrial cancer remains to be demonstrated.

In tissue specimens from patients with cervical cancer, VEGF expression has been noted immunohistochemically in 94% of samples (Loncaster et al 2000). Intratumour levels of VEGF are increased in patients with cervical cancer compared with levels in normal cervical tissue. For these women with cervical cancer, increasing intratumoural levels of VEGF also correlated with higher stage, increased risk of lymphovascular space invasion, greater likelihood of parametrial spread, and lymph node metastasis (Cheng et al 1999).

The biological and clinical significance of the VEGF pathway in tumour angiogenesis suggests its value as a therapeutic target in gynaecological malignancies. There are three main strategies for inhibition of the VEGF pathway for therapeutic applications. The first is to target VEGF itself, the second is to target VEGFR so as to prevent binding of VEGF, and the third is to inhibit tyrosine kinase activation and downstream signalling with small molecules that work at the intracellular level.

Bevacizumab (Avastin) is the first targeted agent to show significant single-agent activity in ovarian carcinoma. It is a recombinant humanized monoclonal antibody directed against VEGF. Bevacizumab has been tested in a number of phase II trials as monotherapy in epithelial ovarian cancer (EOC). Two such trials using single-agent bevacizumab in relapsed high-grade carcinoma of the ovary were presented at the American Society of Clinical Oncology (ASCO) meetings in 2005 and 2006 (Burger et al 2007, Cannistra et al 2007). They convincingly demonstrate bevacizumab's significant single-agent activity in patients with relapsed EOC, with objective response rates (ORR) of 21% and 16%, respectively. Additionally, 52% and 64% of cases, respectively, achieved disease stabilization with median progres-

sion-free survival (PFS) of 4.4 and 4.5 months. These results are as good or better than typical rates from traditional second-line chemotherapeutic agents in this group of patients.

Cytotoxic and antiangiogenic agents can be used in combination for enhanced activity. It has been hypothesized that combining VEGF-targeted agents with frequently administered low-dose so-called 'metronomic chemotherapy' may have additive or synergistic antiangiogenic or antitumour effects. In 2005, Garcia et al presented preliminary data from a phase II trial of patients with recurrent ovarian cancer who were given bevacizumab biweekly with metronomic oral cyclophosphamide. The ORR was 28% and a further substantial proportion (57%) achieved disease stabilization for at least 6 months. The median PFS was 7.5 months and OS was 13 months. This protocol is now closed and the data are undergoing final analysis, but if consistent with preliminary results, these findings would provide the rationale for a phase II randomized trial of combination versus single-agent therapy. Additional reports of outcomes for patients with EOC and primary peritoneal cancer treated with bevacizumab include three historical case series of patients treated outside clinical trials with single-agent therapy or in combination with cytotoxic drugs, suggesting activity in more heavily pretreated patients with recurrent disease, and preliminary data in 2006 demonstrating the feasibility of the combination of traditional carboplatin/paclitaxel chemotherapy combined with bevacizumab in front-line therapy (Cohn et al 2006, Monk et al 2006, Penson et al 2006, Wright et al 2006a).

Based on the encouraging phase II trial data, bevacizumab has been rapidly incorporated into phase III trials, the major focus of which is on first-line treatment. Two similar randomized trials are now underway. The Gynaecologic Oncology Group 218 trial is designed to explore the role of bevacizumab in first-line treatment and in the maintenance setting, with a three-way randomization whereby all patients receive carboplatin/paclitaxel plus bevacizumab or placebo for six cycles, with those receiving bevacizumab further randomized to drug or placebo maintenance for 15 months, with the primary endpoint being OS. It is limited to patients with stage III or IV disease. In contrast, the Gynaecological Cancer Intergroup trial (ICON 7) is a non-placebo-controlled, smaller, two-arm trial in which patients receive either carboplatin/paclitaxel for six cycles or the same treatment plus bevacizumab every 3 weeks during chemotherapy and continuing for an additional 9 months, with the primary endpoint being PFS. The patient population for this trial includes all patients with at least high-risk, early-stage disease. Bevacizumab has also been tested in the phase II setting in combination with topotecan in women with platinum-refractory ovarian cancer (McGonigle et al 2008). To date, 22 patients have been enrolled, 18 of whom were evaluable; 22.2% had a partial response (PR) and 27.8% achieved disease stabilization. Toxicity was described as being acceptable.

Bevacizumab has also been given to women with cervical carcinoma. Wright et al (2006b) gave combination bevacizumab and 5-fluorouracil or capecitabine to women with recurrent cervical cancer. In this small retrospective group of six women, one patient achieved a complete response (CR), one achieved a PR and two achieved disease stabilization.

Unfortunately, all four women eventually had disease progression at a median time of 4.3 months, and none had a progression-free interval of more than 6 months.

Unique toxicities have been ascribed to the administration of bevacizumab and other anti-VEGF molecules. Most of these toxicities (such as proteinuria, hypertension and bleeding) are generally mild and are either self-limiting or easily manageable. Other adverse effects, although uncommon, may be serious; these include arterial thromboembolism, wound-healing complications, and gastrointestinal perforation or fistulae.

Targeting the VEGF/VEGFR axis may affect the survival of both proliferating and quiescent endothelial cells, leading to the disruption of normal vasculature. The increase in arterial thromboembolic events, including cerebral infarction, transient ischaemic attacks, myocardial infarction and angina, may be related to this phenomenon. Hypertension is one of the most common side-effects of bevacizumab therapy, with an overall incidence of 22–32% (Gordon and Cunningham 2005). The mechanism responsible for bevacizumab-related hypertension is not fully understood, but it is thought to be related to decreased production of nitric oxide as a result of VEGF inhibition. Most patients with hypertension can be managed with oral antihypertensive agents.

VEGF is known to play a critical role in the physiological angiogenesis required for wound healing. This could be of particular importance when considering antiangiogenic therapy as front-line adjuvant treatment of ovarian cancer after cytoreductive surgery. Concerns about wound healing in postoperative patients have resulted in the decision to start bevacizumab/placebo therapy at cycle 2 within the Gynaecologic Oncology Group 218 trial. This would be more than 28 days after surgery.

The complication of bowel perforation is now well documented with bevacizumab and, although uncommon, is of concern. It has been suggested that the number of prior cytotoxic regimens and the presence of bowel obstruction might predispose to this complication, although our ability to identify high-risk patients requires further investigation.

Other agents targeting the VEGF pathway are also being developed rapidly. VEGF-Trap inactivates VEGF by acting as a decoy receptor for VEGF, preventing binding of the ligand to its natural receptors. Promising data have been reported regarding VEGF-Trap in preclinical and phase I studies in patients with advanced solid malignancies (Dupont et al 2004, Hu et al 2005). One patient in the phase I study had carboplatin-, taxane- and gemcitabine-resistant advanced ovarian cancer and achieved a response evaluation criteria in solid tumours (RECIST)-defined PR, a 67% reduction in CA125 levels, radiographic resolution of abdominal ascites and subjective improvement of performance status after four cycles of VEGF-Trap. It is currently being evaluated in the phase II setting in patients with recurrent ovarian carcinoma.

Cediranib (AZD2171) is a potent oral tyrosine kinase inhibitor (TKI) of VEGF1, 2, 3 and c-Kit. It has been tested in a phase II study reported at the ASCO meeting in 2008 as a single agent in recurrent ovarian, peritoneal or tubal cancer (Matulonis et al 2008). Preliminary results from 28 patients, 16 of whom had platinum-resistant disease, revealed an ORR of 18.5%. Common toxicities included hypertension ($n = 13$), fatigue ($n = 5$) and diarrhoea ($n = 3$). A further

phase II study of this agent, reported in 2008, has shown similar promising efficacy data and toxicity profiles (Hirte et al 2008).

Sunitinib, an oral multitargeted TKI known to be effective against, amongst others, VEGFR and PDGF receptors, has recently been tested in the phase II setting as a single agent in patients with EOC, primary peritoneal and fallopian tube cancers (Biagi et al 2008). Preliminary results reported at the ASCO meeting in 2008 revealed that 12 out of 17 patients had a PR or disease stabilization. The tolerability profile of this drug is well known from its extensive use in other tumour types, and includes fatigue, mucositis, dysgeusia, hypertension, nausea and hand-foot reaction. Further studies involving larger patient groups are warranted in order to further assess the efficacy of sunitinib in gynaecological cancers.

Sorafenib, another multitargeted TKI (predominantly affecting VEGFR, PDGF receptors, Flt3 and c-Kit) has also been tested in the phase II setting in patients with recurrent EOC and primary peritoneal cancer, the results of which were presented at the recent ASCO meeting (Matel et al 2008). Seventy-three patients who had persistent or recurrent EOC who had been treated previously with one or two cytotoxic regimens, and who had progressed within 12 months of platinum-based therapy, were treated until disease progression or toxicity requiring cessation. The primary endpoint was PFS at 6 months. Response, OS and toxicity were also documented. Toxicities (grade three to four) included rash ($n = 12$), metabolic ($n = 10$), gastrointestinal ($n = 3$), cardiovascular ($n = 2$) and pulmonary ($n = 2$). Twelve out of 59 evaluable patients were progression free for at least 6 months. Two PRs were reported and 20 patients achieved disease stabilization. Mature data are awaited to further define the utility of this agent.

Sorafenib has also been studied in patients with uterine cancer in the phase II setting, and preliminary results have been reported (Nimeiri et al 2008). Patients with advanced or recurrent disease who had experienced one or fewer prior regimens were treated with sorafenib 400 mg bd. Fifty-five patients were enrolled. Grade three to four toxicities included hypertension (13%), hand-foot syndrome (13%) and anaemia (6%). The response rate in patients with advanced/recurrent disease was 5% (PR), and 50% of patients achieved disease stabilization. The median OS was 10.1 months. In patients with carcinosarcoma, 27% achieved disease stabilization. The completion of the trial is awaited.

The Epidermal Growth Factor Receptor Family

The human epidermal growth factor receptor (EGFR) family of transmembrane receptor tyrosine kinases has four identified members: EGFR or HER1, HER2, HER3 and HER4. This subgroup of receptors mediate cell growth, differentiation and survival, and are dysregulated in many types of cancer. Ligand binding to the extracellular domain of the receptors enables receptor homo- or heterodimerization, which initiates phosphorylation of the intracellular tyrosine kinase domain and activation of cell signalling to reduce apoptosis and increase tumour cell proliferation.

The HER pathway is involved in ovarian cancer pathogenesis (Berchuck et al 1990, Bartlett et al 1996, Campiglio et al

1999). The majority of ovarian cancer cell lines and tumours express high levels of a number of HER receptor ligands, as well as exhibiting amplification of EGFR and HER2, and expressing all HER receptors (Campiglio et al 1999). In EOC, attention has focused on EGFR (HER1) which is expressed in 19–92% of tumours, and expression of which is associated with a poor prognosis (Ford et al 1994, Lin et al 1994, Goff et al 1996, Ilekis et al 1997, Fischer-Colbrie et al 1997).

The goal of EGFR-targeted therapies is to disrupt phosphorylation, thereby increasing apoptosis and reducing cell proliferation signals. This disruption can be achieved in several ways: inhibition of dimerization, blocking of EGFR receptor ligand binding with humanized monoclonal antibodies, and inhibition of tyrosine kinase activity with small-molecule TKIs. In the majority of trials of anti-EGFR agents in patients with EOC, the agents are investigated as monotherapy in heavily pretreated women. Objective responses are relatively low but prolonged disease stabilization has been seen in a subset of women.

The small-molecule TKIs erlotinib (Tarceva) and gefitinib (Iressa) have been tested in phase II trials of patients with relapsed and pretreated EOC. A trial of erlotinib as monotherapy in women with advanced EGFR-positive cancers treated with a mean of three prior regimens was presented at the ASCO meeting in 2001 (Finkler et al 2001). The ORR was 8.8%, with a further 7% of patients achieving disease stabilization for more than 6 months. A similar trial of gefitinib in patients with recurrent or persistent ovarian carcinoma or primary peritoneal cancer, but in which EGFR expression was not required for inclusion, led to a response rate of only 3.7% and long-term disease stabilization for more than 6 months in a further 14.8% of patients (Schilder et al 2003). The median time to progression was approximately 2 months, but 10% of patients remained progression free at 8–12 months. Interestingly, all of these patients had EGFR-positive tumours. Unlike in lung cancer, where EGFR expression and the presence of a mutation in the tyrosine kinase domain of EGFR confer sensitivity to EGFR TKIs, the relationship between EGFR positivity, EGFR mutation and response to EGFR TKIs is not clearly defined in EOC. Better definition of this relationship may help to identify the subset of women with EOC that are likely to achieve clinically meaningful responses to TKIs, and therefore define the appropriate treatment population.

Monoclonal antibodies against EGFR have also been investigated. The most established anti-EGFR antibody is cetuximab (Erbix). This has been evaluated in previously untreated women with EOC in combination with standard first-line carboplatin/paclitaxel chemotherapy and as maintenance therapy. An ORR of 87% was seen and toxicity was acceptable (Aghajanian et al 2005). Its use as monotherapy is currently under investigation. Another anti-EGFR monoclonal antibody, matuzumab, has been investigated in women with recurrent EGFR-positive EOC (Seiden et al 2005); although no objective responses were seen, 21% of women achieved disease stabilization for more than 6 months.

Monoclonal antibodies directed against HER2 have also been investigated in advanced EOC. Laboratory studies have suggested that 10–15% of women have tumours that overexpress HER2 graded as 2+ or 3+ positivity by immunohis-

tochemistry (IHC). It is unclear whether this is predictive of clinical outcome in EOC. In breast cancer, where the role of HER2 receptor overexpression is well defined, it is only a predictive factor in those with IHC 3+ positivity and it is only this subset who derive clinical benefit from anti-HER2 therapies (Slamon et al 2001). In a phase II study of the anti-HER2 monoclonal antibody trastuzumab (Herceptin) in EOC, of the 837 patients who were registered and screened, only 95 (11%) had tumours with grade 2+ or 3+ positivity. Of these patients, only 41 were treated, with an ORR of only 7.3% (Bookman et al 2003). The study concluded that the clinical value of single-agent trastuzumab in recurrent ovarian cancer is limited by the low frequency of HER2 overexpression and low rate of objective response among patients with HER2 overexpression.

The monoclonal antibody pertuzumab was the first in a new class of targeted anticancer agents termed 'HER dimerization inhibitors'. It binds to the dimerization site of HER2, inhibiting its interaction with other HER family members. Unlike HER1, -3 and -4, HER2 has no known ligand and assumes an open conformation, with its dimerization domain permanently exposed for interaction with other ligand-activated HER receptors. HER2 is the preferred partner for dimer formation, and subsequent pathway activation via receptor phosphorylation has been shown to drive ovarian tumour cell proliferation, even in the absence of HER2 overexpression. Pertuzumab was investigated as monotherapy in a phase II trial in patients with advanced, refractory or recurrent ovarian cancer (Gordon et al 2006). A PR was achieved in 4.3% of subjects, with 41% achieving disease stabilization. However, median PFS was 20.9 weeks for HER2-positive patients compared with 5.8 weeks for HER2-negative patients and 9.1 weeks for those of unknown HER2 status. It should be noted that these patients were heavily pretreated and the median number of prior therapies was five. The study concluded that given that pertuzumab blocks all HER2-mediated signalling, in contrast to targeted blockade of EGFR or HER2 overexpression, pertuzumab may result in higher rates of clinical activity in an appropriately selected population. A randomized phase II study evaluating the combination of carboplatin-based chemotherapy with pertuzumab in comparison with carboplatin-based therapy alone in patients with relapsed, platinum-sensitive ovarian cancer is currently underway. Preliminary data presented at the ASCO meeting in 2008 reveal that the addition of pertuzumab to carboplatin-based chemotherapy is well tolerated, but efficacy data are awaited.

The small-molecule TKI lapatinib is similar to gefitinib and erlotinib, except that it has similar specificity for EGFR and HER2. Data from initial clinical experience with lapatinib have only shown mild adverse events (rash, diarrhoea, nausea, vomiting) and no grade four events. In the original phase I trial, three subjects showed a PR and 12 patients achieved disease stabilization, including two with ovarian cancer (Spector et al 2005).

Poly(ADP-Ribose) Polymerase Inhibitors

BRCA1 and *BRCA2* belong to a class of genes known as tumour suppressor genes. Their protein products are important for DNA double-strand break repair (Tutt and Ashworth

2002). Mutations in *BRCA1* and *BRCA2* predispose to a number of hereditary cancers, including breast and ovarian. Poly(ADP-ribose) polymerase (PARP) is a DNA-binding enzyme involved in base excision repair, a key pathway in the repair of DNA single-strand breaks. Tumours in carriers of *BRCA1* or *BRCA2* mutations lack wild-type *BRCA1* or *BRCA2*, but normal tissues retain a single wild-type copy of the relevant gene. This biochemical difference provides the rationale for an approach involving PARP inhibition to generate specific DNA lesions that require functional *BRCA1* and *BRCA2* for their repair. In a study by Farmer et al in 2005, *BRCA1* and *BRCA2* dysfunction was shown to profoundly sensitize cells to the inhibition of PARP enzymatic activity, resulting in chromosomal instability, cell cycle arrest and subsequent apoptosis. In other words, PARP inhibitors were found to be selectively cytotoxic to tumours lacking *BRCA1* and *BRCA2*, where the specific mechanism that repairs damaged DNA is absent. In addition, PARP inhibitors have been shown to significantly enhance the effect of a number of widely used cytotoxics that damage DNA. Results from a phase I study of AZD2281, a novel, potent, orally active PARP inhibitor in patients with *BRCA*-deficient ovarian cancer, were presented at the ASCO meeting in 2008 (Fong et al 2008). The study demonstrated compelling activity in patients with *BRCA*-deficient ovarian cancer, with efficacy data revealing a PR rate of 44% and a further 25% of patients achieving disease stabilization. AZD2281 was well tolerated, toxicities being mainly gastrointestinal and mild, and little myelosuppression was seen. A randomized study of AZD2281 in *BRCA*-deficient ovarian cancer is planned.

mTOR

It is known that intracellular signal transduction pathways interact to regulate the cell cycle, apoptosis, cytoskeletal organization and senescence. An example of this is the mammalian target of rapamycin (mTOR), a serine/threonine protein kinase that is a central regulator of cell growth, proliferation and survival (Beevers et al 2006). mTOR, in turn, is regulated by the phosphatidylinositol3-kinase (PI3K)/AKT pathway, a signalling cascade that is aberrant in over 70% of tumours (Meric-Bernstam and Mills 2004). Dysregulation of this pathway has been demonstrated in ovarian cancer.

The inhibition of mTOR results in a profound decrease in the transmission of proliferative signals through the PI3K/AKT pathway, leading to antiproliferative effects and angiogenesis inhibition. IHC analysis of ovarian cancer specimens has shown that both AKT and mTOR are frequently activated (phosphorylated) in these tumours (Altomare et al 2004). In the same study, the effects of AKT/mTOR activation on the therapeutic sensitivity of ovarian cancer cells to cytotoxic agents was tested. Augmentation of cisplatin-induced apoptosis was seen in cells exhibiting constitutive AKT activity when pretreated with the PI3K inhibitor LY294002. In contrast, ovarian cancer cell lines with low basal levels of AKT activity did not show increased cisplatin-induced apoptosis. In addition, inhibition of mTOR activity with rapamycin resulted in cell cycle arrest in those cells exhibiting constitutive AKT activity, but not in those cells with low levels of

AKT activity. Collectively, these findings indicate that active AKT and downstream mTOR represent potentially important therapeutic targets in ovarian cancer.

Preclinical studies have demonstrated that rapamycin (a highly specific inhibitor of mTOR kinase) and its analogues inhibit proliferation not only in ovarian cancer cell lines but also in cervical and endometrial cancer cell lines, and in a broad range of murine syngeneic tumour models and human xenografts. Three rapamycin analogues are currently in clinical development as anticancer agents: AP23573, CCI-779 (temsirolimus) and RAD001 (everolimus).

AP23573 has been tested in a phase I trial in patients with advanced solid malignancies (Mita et al 2004). The dose-limiting toxicity was mucositis, and common treatment-related adverse events included mouth sores and rash. Four out of 32 (12.5%) patients experienced a confirmed PR and three (9%) additional patients had minor tumour regression. AP23573 has also been tested in a phase Ib combination trial with paclitaxel in patients with progressive solid tumours (Cresta et al 2007). The dose-limiting toxicities were mucositis, fatigue, myelotoxicity with prolonged moderate neutropenia, and skin rash. Pharmacodynamic analysis in peripheral blood mononuclear cells demonstrated no interference by paclitaxel on mTOR inhibition by AP23573. The trial concluded that combined therapy with AP23573 and paclitaxel is feasible and well tolerated, and recommended evaluation of the combination in phase II trials examining efficacy in specific tumours.

Preliminary results of a phase II trial of single-agent AP23573 in patients with advanced metastatic endometrial cancer were presented at the ASCO meeting in 2007 (Colombo et al 2007). The trial involved 45 patients, all of whom had progressive disease. The primary endpoint was a clinical benefit response, defined as a CR or PR or prolonged disease stabilization for at least four cycles. This was achieved, with 29% of patients having a clinical benefit response, including 10% with a PR. The most common toxicities were mucositis, fatigue, anaemia, diarrhoea and nausea/vomiting. This study reveals promising results of single-agent AP23573 in progressing endometrial cancer, and warrants further evaluation of the drug as monotherapy and in combination with other agents.

In preclinical models, CCI-779 or temsirolimus, an ester derivative of rapamycin, has shown antitumour effects across a wide variety of tumour types. An initial dose-escalation phase I trial administered temsirolimus weekly (Raymond et al 2004). Although thrombocytopenia was dose limiting and a reversible maculopapular rash and stomatitis were observed, the formal definition of a maximum tolerated dose was not met. In addition, objective partial and minor responses were observed at lower dose levels. Encouraging data from a phase II study of single-agent temsirolimus in chemotherapy-naïve patients with metastatic or recurrent endometrial cancer were presented at the ASCO meeting in 2006 (Oza et al 2006). The ORR was 21%, with 48% of patients achieving prolonged disease stabilization. These results are equivalent to those of currently used cytotoxic chemotherapy. A subsequent phase II study assessed the level of activity of temsirolimus in patients with metastatic and/or locally advanced recurrent endometrial cancer who had previously received chemotherapy (Oza et al 2008). The results of this study indicated that temsirolimus had modest

activity, with only 7.4% of patients achieving a PR; however, 44% achieved disease stabilization with a mean duration of 3.5 months. A phase II trial of temsirolimus in the treatment of persistent or recurrent EOC or primary peritoneal cancer is currently underway.

RAD001 (everolimus) is an oral rapamycin analogue that selectively inhibits mTOR. It has shown encouraging single-agent clinical benefit in pretreated patients with recurrent endometrial carcinoma in a phase II study presented at the ASCO meeting in 2008 (Slomovitz et al 2008). Although none of the patients achieved a PR, 44% of patients achieved disease stabilization of more than 8 weeks. Interestingly, loss of *PTEN* expression, a tumour suppressor gene found in 40–60% of endometrial cancers, the loss of which leads to constitutive AKT activation and upregulation of mTOR activity, was found to be predictive of prolonged disease stabilization.

Protein kinase C

Protein kinase C (PKC) is a family of serine/threonine protein kinases which are centrally involved with the regulation of angiogenesis, cell growth and survival. Activated PKC- β promotes VEGF-mediated angiogenesis and has been implicated in the progression of malignancy, cell proliferation and inhibition of apoptosis. The activated form of PKC- β has been identified in a number of human tumours, including ovarian cancer.

Enzastaurin, an oral selective inhibitor of the PKC- β isozyme, has been shown to have antiangiogenic effects and to promote apoptosis by downregulating signalling through the PI3K pathway in several cancers (Graff et al 2005, Lee et al 2008). Preclinical studies have shown enzastaurin to have anticancer effects as a single agent and in combination with carboplatin and paclitaxel in breast and ovarian carcinomas (Teicher et al 2002, Keyes et al 2004). In a study of the effect of enzastaurin on ovarian cancer cell lines with selective resistance against various cytostatic drugs, taxane-resistant cells showed the most prominent response to low concentrations of enzastaurin (Meinhold-Heerlein et al 2006). In phase I trials, prolonged stabilization of disease was seen in several patients treated with enzastaurin, with acceptable toxicities (Carducci et al 2006). Synergistic activity with standard-of-care chemotherapies was seen, with no significant alterations in the pharmacokinetic variables of the cytotoxic drugs with which it was combined (Beerepoot et al 2006, Rademaker-Lakhai et al 2007). Enzastaurin is now being tested in ovarian cancer in the phase II setting by the Gynaecologic Oncology Group.

CA125

CA125 is a surface antigen that is expressed on the majority of EOCs and occurs at elevated levels in the serum of patients with ovarian cancer. Serum levels of CA125 are used to monitor responses to chemotherapy, relapse and disease progression in ovarian cancer patients. In 2001, the gene for the peptide moiety of CA125 was cloned and termed '*MUC16*' because of its similarities to the mucin family of proteins (Yin and Lloyd 2001). The biological

functions of CA125 are complex but, based on current knowledge, CA125 seems to enhance the malignant potential of ovarian cancer cells.

Monoclonal antibodies that target CA125 are now in development as a therapeutic strategy. One such drug, ovregovomab (Mab-813.13, Ovarex), behaves as an immunotherapeutic agent. Infusion of low-dose antibody results in the formation of circulating immune complexes which can trigger a cellular immune response targeting CA125 and the ovarian cancer. Reported data have shown an association between intratumoral T cells and improved clinical outcome, lending support for immune-mediated disease control (Zhang et al 2003). Ovregovomab has been compared with placebo in a randomized trial of women with ovarian cancer who had achieved complete remission after first-line chemotherapy. There was no OS advantage but subset analysis showed that half of the treated women generated an immune response to ovregovomab, and these women had superior survival to those without an immune response (Ehlen 2002, Berek et al 2004).

A phase III randomized trial was reported at the ASCO meeting in 2008 of maintenance ovregovomab monotherapy versus placebo in patients with stage III/IV ovarian cancer (Berek et al 2008). Patients were treated until recurrence or for up to 5 years, and the primary endpoint was time to recurrence. Three hundred and seventy-one patients were randomized, but unfortunately there were no significant differences in the clinical outcomes between the two groups. Conclusions drawn were that although it was not effective as a single agent, its use in combination with other cytotoxic agents should be investigated further. Ovregovomab has been evaluated in combination with carboplatin/paclitaxel as front-line chemoimmunotherapy in patients with advanced ovarian cancer (Brady et al 2007). Chemotherapy-induced bone marrow suppression has been assumed to inhibit the generation of augmented immune responses; however, contrary to expectations, concurrent carboplatin/paclitaxel resulted in enhanced immune stimulation with ovregovomab.

A second drug, abagovomab (formerly ACA125), is an antibody which functionally mimics the CA125 antigen and induces humoral and cellular CA125-specific immunity. Abagovomab has been shown to generate immune responses in women with EOC (Wagner et al 2001). Indeed, those women who generated an immune response had a mean survival of 19.9 ± 3.1 months, compared with 5.3 ± 4.3 months in those women who did not develop a response. Efficacy testing is underway, although it is not yet clear whether this strategy will have clinical impact in EOC.

Src

Src, a non-receptor tyrosine kinase, is an attractive therapeutic target in ovarian cancer because it is expressed and activated in the majority of ovarian cancers and regulates a myriad of intracellular signal cascades responsible for critical tumour cell functions, including cell proliferation and differentiation, through extracellular stimulation by growth factors, growth hormones and integrins (Ishizawa and Parsons 2004). Moreover, the emerging role of Src in angiogenesis has recently been noted because of its upregu-

lation of proangiogenic cytokines such as VEGF and interleukin-8 (Summy et al 2005). The ability of VEGF to disrupt endothelial barrier function, which has been correlated with tumour cell extravasation and metastasis, is mediated through Src.

Src has been found to be overexpressed in the majority of late-stage ovarian tumours, as well as a panel of ovarian cancer cell lines (Wiener et al 2003). A study by Han et al in 2006 showed that Src inhibition, through a novel small-molecule inhibitor AP23994, alone and in combination with cytotoxic chemotherapy, significantly reduced tumour growth *in vivo* in both chemotherapy-sensitive and chemotherapy-resistant preclinical ovarian cancer models. They concluded that Src inhibition might be an attractive therapeutic approach for patients with ovarian carcinoma.

Alpha Folate Receptor

Alpha folate receptor is a membrane-bound protein with high affinity for binding and transporting physiological levels of folate into cells. Folate is a basic component of cell metabolism and DNA synthesis and repair. Rapidly dividing cancer cells have an increased requirement for folate to maintain DNA synthesis; an observation supported by the widespread use of antifolates in cancer chemotherapy. Alpha folate receptor is overexpressed in the majority of EOCs but is largely absent from normal tissue. Overexpression is associated with increased tumour aggressiveness (Toffoli et al 1997). MORAb-003 is a humanized monoclonal antibody against alpha folate receptor. Binding of MORAb-003 to alpha folate receptor blocks phosphorylation, mediates the killing of alpha-folate-receptor-expressing tumour cells, and suppresses tumour growth in xenograft models. A phase I study of single-agent MORAb-003 showed no dose-limiting toxicities and no significant adverse events, and suggested efficacy in platinum-resistant EOC (Bell-McGuinn et al 2008).

A phase II trial of MORAb-003 as monotherapy or in combination with platinum and taxane in women with recurrent, platinum-sensitive EOC was presented at the ASCO meeting in 2008 (Armstrong et al 2008). In subjects receiving MORAb-003 with platinum and taxane, CA125 normalized in 58% of women after two cycles, 88% of women after four cycles and 100% of subjects after six cycles; RECIST scores of measurable disease improved in parallel. This is a significant increase in ORR compared with historical data for platinum/taxane alone. Based on these data, additional studies of MORAb-003 with chemotherapy in platinum-sensitive and platinum-resistant EOC are planned.

Novel Taxanes

Paclitaxel conjugates have an extended half-life compared with paclitaxel, leading to increased exposure of a tumour to the agent. One such agent that has shown activity in both platinum-sensitive and platinum-resistant ovarian cancer is CT2103. A phase II study of CT2103 in 99 heavily pretreated patients with recurrent ovarian, fallopian tube or peritoneal cancer has been carried out. Platinum-sensitive

($n = 42$) and platinum-refractory/-resistant ($n = 57$) patients were recruited, 61% of whom had received between three and 12 prior regimens (Sabbatini et al 2004). The response rate was 14% and 7% in platinum-sensitive patients and platinum-resistant patients, respectively, with a median time to progression of 2 months. Common toxicities reported were neuropathy (30% grade two or three) and hypersensitivity (8%).

Epothilones

Like the taxanes, epothilones are microtubule stabilizers and have activity against cancer cell lines which are resistant to paclitaxel and other cytotoxic drugs (Rowinsky 1997). They show activity in taxane-resistant tumours *in vivo* (Kolman 2005). This is partially due to the fact that they are not substrates for multidrug transporter proteins. Epothilone B (patupilone) has led to disease stabilization and responses in the phase I/II setting in various malignancies including cancer of the ovary, prostate, breast, colon, stomach and kidney (Mani et al 2004). Six epothilones are in early clinical trials for cancer treatment. Dilawari et al (2008) reported an expanded phase I study of ixabepilone 40 mg/m² in patients previously treated with taxanes ($n = 44$) who had ovarian, endometrial, fallopian tube, cervical, breast or another cancer. A range of one to 14 cycles was given, primarily to examine activity and neurotoxicity. Tumour marker response was seen in one-quarter of patients. Three patients had a PR and two had a minimal response. One-quarter of the patients had grade two to three neuropathy, which was preceded by vibration perception threshold changes. Other toxicities included hypersensitivity ($n = 1$) and neutropenia (grade three or more in 18 patients). There are also phase I data on the epothilone patupilone (EPO 906), both as a single agent and in combination with other chemotherapeutics, such as carboplatin (Gore et al 2005, Smit et al 2005, Bagstrom et al 2008, Fracasso et al 2008, Reid et al 2008).

Miscellaneous

Trabectedin (Yondelis, ecteinascidin-743) is a tetrahydroisoquinoline alkaloid derived from a Mediterranean marine organism which is able to bind to the minor groove in DNA. It thereby affects transcription factors involved in cell proliferation, blocks cell division in the G(2) phase and inhibits overexpression of the multidrug resistance-1 gene that leads to development of resistance to many anticancer drugs. It also interferes with nucleotide excision repair. Two phase II trials have reported single-agent activity in patients with platinum-sensitive and platinum-refractory recurrent ovarian cancer (Sessa et al 2005, Krasner et al 2007). In the platinum-sensitive group, 62 evaluable patients had an ORR of 29% [95% confidence interval (CI) 18.2–41.9] and median PFS was 5.1 months (95% CI 2.8–6.2). In the platinum-resistant group, out of 79 evaluable patients, the ORR was 6.3% (95% CI 2.1–14.2) and median PFS was 2 months (95% CI 1.7–3.5). The toxicity profile was manageable with 10% of patients having alanine aminotransferase elevation and 8% of patients having neutropenia (Krasner et al 2007).

A second phase II study including patients with ovarian cancer resistant to platinum and taxanes ($n = 30$) or not ($n = 29$) has been reported (Sessa et al 2005). After two, three-weekly cycles, two PRs were seen and other responses were evident for up to 12.9 months (median 5 months). In the platinum-sensitive group, response rates were 43% (95% CI 23–65). The treatment was well tolerated.

The drug TLK-286 is thought to work by inhibiting glutathione-S-transferaseII, a detoxifying mechanism. A phase II study recruited 36 patients with platinum- and paclitaxel-refractory or -resistant ovarian carcinoma (Kavanagh et al 2005). Of the 94% of patients that were evaluable for response, 15% had objective tumour responses, one had a CR and four had a PR. Twelve patients achieved disease stabilization and this was associated with a decrease in CA125 and improvement in performance status. Median survival was 423 days. The compound was well tolerated and phase III studies are now underway.

A study investigating the additive benefit of proteasome inhibition in combination with liposomal doxorubicin in platinum-sensitive ($n = 15$) and platinum-resistant ($n = 15$) patients was reported at the ASCO meeting in 2008 (Scambia et al 2008). Preliminary results in the platinum-resistant cohort of patients showed prolonged disease stabilization, and four PRs were seen in the platinum-sensitive cohort. The main adverse events were gastrointestinal (77% grade two or less), neurotoxicity (25% grade two or less) and haematological toxicity (21% grade three or less). The study is still open and complete results are awaited with interest to further define the possible synergy with this combination.

Brostacillin is a drug that forms a covalent interaction with DNA when glutathione is present. Twenty-one platinum-resistant and platinum-refractory patients with EOC were treated with brostacillin in a phase II study (Lorusso et al 2008). Two patients had a PR which lasted over 6 months, one patient achieved disease stabilization for 24 weeks and the rest of the patients progressed. Reported toxicity included haematological toxicity (neutropenia in 71% of patients and thrombocytopenia in 43%) and weight decrease (9.5%). Further studies were felt to be warranted to further investigate the use of brostacillin in this patient group.

Integrins are molecules which are vital in forming cell-to-cell adhesions. Volociximab is an $\alpha 5\beta 1$ integrin antibody that has been tested in patients with relapsed advanced EOC and primary peritoneal carcinoma in the phase I/II setting (Delmonte and Sessa 2008). Three patients were treated with 7 mg/kg qwk and six patients were treated with 15 mg/kg qwk in combination with liposomal doxorubicin until disease progression. Preliminary data suggest that this is a well-tolerated combination, with the main toxicities reported as asthenia ($n = 6$), nausea ($n = 3$), abdominal pain ($n = 2$), flu-like symptoms ($n = 2$) and vomiting ($n = 1$). A phase II study is planned comparing liposomal doxorubicin alone with the combination of liposomal doxorubicin and volociximab.

Farnesyl transferase inhibitors block the activity of the RAS oncoprotein in tumours. BMS-214662 is a farnesyl transferase inhibitor that has been tested in the phase I setting in patients with advanced solid tumours in combination with paclitaxel and carboplatin (Dy et al 2005). Paclitaxel and carboplatin were given three weekly, and

escalating doses of BMS-214662 were given on the first day of each cycle. Thirty patients were treated, and no pharmacokinetic interactions were seen between the three drugs. One patient with endometrial cancer and one patient with ovarian cancer had a PR. Disease stabilization was achieved in eight other patients. The combination was well tolerated with dose-limiting toxicities including neutropenia, thrombocytopenia, nausea and vomiting. A further phase I study tested BMS-214662 in combination with paclitaxel alone in patients with advanced solid tumours. Patients were treated ($n = 26$) with weekly paclitaxel and escalating doses of BMS-214662, and up to 94 courses of treatment (Bailey et al 2007). All the pretreated ovarian cancer patients had a PR, and pharmacokinetic studies showed no interaction with paclitaxel. Peripheral blood lymphocytes (PBLs) were taken to test for significant farnesyl transferase inhibition (>80%), which was seen at the end of the BMS-214662 infusion. Dose-limiting toxicities included grade four neutropenia, rises in serum transaminases and grade three diarrhoea.

Histone deacetylase (HDAC) inhibitors block the deacetylation of histones, a mechanism by which the regulation of gene expression is mediated. Two phase II studies were reported at the ASCO meeting in 2008 detailing results of HDAC inhibition in platinum-resistant epithelial ovarian tumours. The first study used belinostat (PXD101) in platinum-resistant patients ($n = 18$, group 1) or patients with micropapillary/borderline ovarian tumours ($n = 12$, group 2) (Mackay et al 2008). Tumour biopsies and PBLs were taken prior to treatment, and on the fourth day (out of 5 days) of treatment. Of the patients in group 1, nine patients achieved disease stabilization and six progressed. Of the patients in group 2, one patient had a PR, nine achieved disease stabilization and one patient had a CA125 response. Grade three adverse events included thrombosis ($n = 3$), dyspnoea ($n = 2$), fatigue ($n = 2$), elevated alkaline phosphatase ($n = 2$) and nausea ($n = 2$). The second study also tested belinostat but in combination with carboplatin and paclitaxel in platinum-resistant and platinum-sensitive patients. Eleven patients relapsed within 6 months of first platinum therapy. The ORR was 31%, which included one CR and 10 PRs. Sixteen patients achieved disease stabilization. Common grade three to four adverse events were neutropenia ($n = 4$), transaminitis ($n = 4$) and fatigue ($n = 3$). Recruitment to both studies is still ongoing.

Conclusion

The treatment of gynaecological malignancies in the future will no doubt make use of our increased understanding of the biology of these diseases. Whether the novel agents discussed above are used alone, in combination with each other or with other chemotherapeutics remains to be defined. The exact benefit of many of these agents in terms of response rates and disease-free survival is also largely unknown. In addition, it is uncertain whether they will simply be unaffordable in most health economies. However, this is certainly an exciting time in the field of gynaecological oncology, and it is hoped that the use of targeted agents will have a significant impact on disease progression and outcome in the near future.

KEY POINTS

1. Advances in the molecular biology of gynaecological malignancies has led to a number of potential therapeutic targets being identified: VEGF, EGFR, PARP, PI3K/AKT, PKC pathways and the alpha folate receptor.
2. Early initiation of angiogenesis is essential for cancer survival, and VEGF expression has been correlated with outcome for gynaecological cancers.
3. A number of antiangiogenic agents are showing activity in gynaecological cancers, including monoclonal antibodies, TKIs and decoy receptor molecules.
4. Mutations in *BRCA1* or *BRCA2* result in specific DNA repair mechanism defects. PARP inhibitors have been shown to be active against such tumours, and also enhance the effect of cytotoxics.
5. Inhibition of mTOR results in a profound decrease in signalling via the PI3K/AKT pathway. mTOR inhibitors have activity in gynaecological malignancies, particularly endometrial cancer.
6. Inhibitors of PKC and Src have potential as targeted therapy against ovarian cancer, and are currently the subject of clinical studies.
7. The alpha folate receptor is overexpressed in the majority of ovarian cancers but is largely absent from normal tissue, and is a promising target.
8. It remains to be defined whether the novel targeted agents will be best utilized as single agents or in combination with each other or cytotoxics.
9. Target agents have the potential to be used as maintenance therapy following remission induction.

THE VULVA	576		

Introduction

The key to the effective management of premalignancy is to understand its aetiology, pathogenesis and natural history. Our knowledge and understanding of premalignant disease of the genital tract has progressed from descriptive morphology to a molecular biological level; a shift that is reflected by the evolution of clinical management from the detection and surgical removal of premalignant lesions to their prevention.

The tissues of the female genital tract differ in terms of embryological origin, responsiveness to intrinsic factors such as hormones, and exposure to external mutagens. Cellular transformation, leading to the development of cancer, is brought about by a variety of events, in part responding to various agents, acting alone or in combination, termed 'carcinogens'. In the female genital tract, these may be viruses, chemicals, hormones or ionizing radiation. It follows that a single chapter under the heading of 'Premalignant disease of the female genital tract' will necessarily cover a variety of issues that are best considered by anatomical site.

The Cervix

In 1886, Sir John Williams described eight cases of cervical cancer, one of which was equivalent to carcinoma *in situ*:

'this is the earliest condition of undoubted cancer of the portio vaginalis that I have met with, and it is the earliest condition that is recognisable as cancer. It presented no distinct symptoms and was discovered accidentally.'

This described the cardinal features of cervical premalignancy; it is asymptomatic, clinically undetectable and has malignant potential. Its recognition had profound therapeutic significance as detection and treatment offered the potential to prevent cancer. The challenge has been to realize this

therapeutic goal effectively with as little collateral damage as possible.

The terminology of cervical premalignancy

Most cervical cancers are squamous in origin, but a significant, and increasing, proportion arise from cervical glandular epithelium (estimates ranging from 5% to 30% of the precancerous lesions found on the cervix). Both cancer types have premalignant lesions.

The premise that cervical squamous premalignancy was a continuum underpinned the concept of cervical intraepithelial neoplasia (CIN), which was suggested by Richart (1967). The usefulness of this system was limited by significant inter-observer variability in the diagnosis and grading of CIN, particularly in differentiating CIN1 from human papilloma virus (HPV) lesions, and separating CIN1 from CIN2 lesions. Furthermore, there is no clear evidence that CIN3 arises from earlier lesions.

These considerations were addressed by the Bethesda classification which was initially introduced as a cervical cytological grading system. Cervical lesions are classified into high- and low-grade squamous intraepithelial lesions; the latter group includes HPV lesions. This has the potential advantage of simplicity and tends to reflect the way in which clinicians practise, in that high-grade lesions are thought to be genuinely premalignant and should be treated.

Currently, whilst CIN terminology is used in the UK, clinical practice reflects the Bethesda classification in that CIN1 is regarded as a low-grade lesion, which tends to be managed conservatively, and CIN2 and CIN3 are regarded as high-grade lesions which are treated.

Attempts to classify premalignant glandular lesions have been bedevilled by a number of problems. In the UK, they are termed 'cervical glandular intraepithelial neoplasia' (CGIN) and are classified as high- or low-grade lesions. Low-grade CGIN lesions are difficult to distinguish from a number

of benign and reactive changes. The biological behaviour of low-grade CGIN is not understood.

Pathology of cervical premalignancy

Cervical intraepithelial neoplasia

CIN relates to lesions that are confined to the squamous epithelium. The diagnosis of CIN is based upon the architectural and cytological appearances of the squamous epithelium. It is characterized by abnormal cellular proliferation, abnormal epithelial maturation and cytological atypia. Grading depends on the level in the epithelium to which abnormal changes extend.

The proportion of the thickness of the epithelium showing differentiation is a useful feature to be taken into account when deciding the severity of a CIN; roughly lower-, middle- and upper-third involvement equate to CIN1, CIN2 and 3, respectively. It is not the most important criterion despite the fact that it is one of the easiest to assess. In CIN1, at least the upper half of the epithelium usually shows good differentiation and stratification, whereas in CIN3, differentiation may be very slight or even absent.

CIN may affect the gland crypts as well as the surface epithelium (Figure 38.1). It is recognized that the degree and depth of crypt involvement increases with the grade of CIN. Histological assessment of crypt involvement in women with CIN3 has shown a mean depth of 1–2 mm, with a maximum of 5.22 mm and a mean ± 3 standard deviations (99.7%) of 3.8 mm (Anderson and Hartley 1980). These figures suggested that treatment of ectocervical lesions to a depth of 7 mm should be sufficient to eradicate most CIN.

Cervical glandular intraepithelial neoplasia

CGIN is characterized by columnar cells with hyperchromatic nuclei and stippled chromatin (Figure 38.2). The nuclei show increased stratification and abnormal mitotic figures with loss of normal mucin. In some cases, the whole

of a gland may be involved, but the lesion often occurs as a sharply demarcated area. It may be multifocal. CGIN is often associated with goblet cells or intestinal metaplasia of the endocervical cells. In two-thirds of cases, there are associated squamous abnormalities, and CGIN is often serendipitously discovered in the management of these abnormalities.

Histological problems

The histological diagnosis of these lesions is based largely upon subjective criteria and is dependent on the adequacy of sampling. It is not surprising to find substantial inter- and intraobserver variation in the grading of CIN and the identification of CGIN. Variation is greatest at the lower end of the spectrum.

These considerations have important implications. Firstly, understanding of the risk of progression of CIN and its subgroups, on which treatment strategies are based, is inevitably flawed by bias of one form or another. Furthermore, in any given patient, there will be a spectrum of disease so that the reliability of the histological diagnosis is dependent on the quality and extent of sampling.

Pathogenesis of cervical premalignancy

The development of squamous precancerous abnormalities is intimately associated with the region of the cervical squamocolumnar junction (SCJ) and the changes that occur at puberty and adolescence.

The position of the SCJ is influenced by the hormonal changes that occur during a woman's life (Figure 38.3). With the onset of puberty, the uterus enlarges and the cervix swells with a resultant eversion, exposing columnar epithelium to the acid environment of the vagina. This induces metaplasia

Figure 38.1 The cervical transformation zone shows the metaplastic squamous epithelium replaced by full-thickness lack of maturation amounting to cervical intraepithelial neoplasia 3 (long arrow). This is seen extending down the gland cleft (block arrow). The inset shows brisk epithelial mitotic activity. Original magnification $\times 100$, inset $\times 200$.

Figure 38.2 High-grade cervical glandular intraepithelial neoplasia, characterized by hyperchromatic glandular cells with pseudostratification, relative paucity of mucin, brisk mitotic activity and abrupt junction with normal epithelium (long arrow). Intestinal metaplasia (short arrow) is noted. Original magnification $\times 40$.

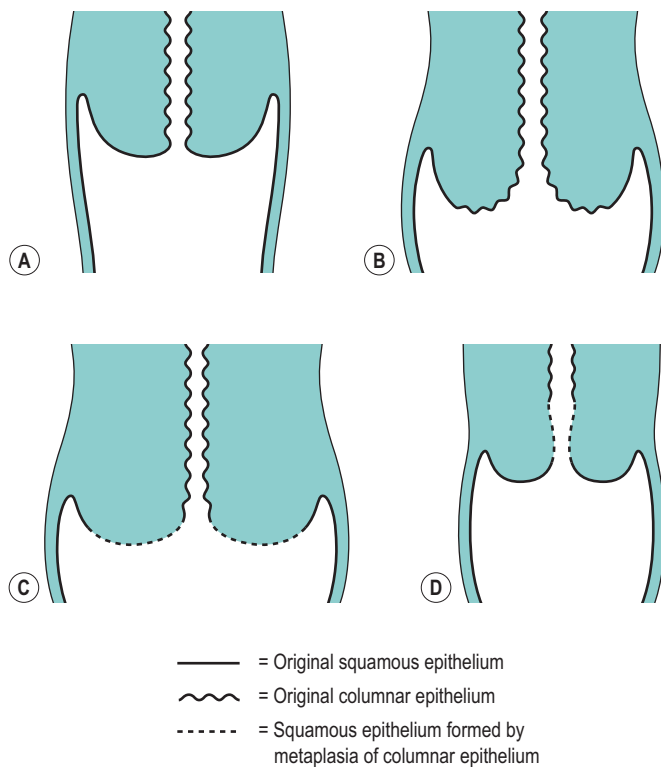

Figure 38.3 The different stages in the development and involution of the cervix. (A) Before puberty, the ectocervix is covered with squamous epithelium, and columnar epithelium is usually confined to the endocervical canal. (B) The cervix enlarges and everts when oestrogen levels rise. This exposes columnar epithelium on the ectocervix. (C) The columnar epithelium on the ectocervix is replaced with squamous epithelium by a process of metaplasia. (D) Following the climacteric when oestrogen levels fall, the cervix shrinks, drawing the squamocolumnar junction up the canal.

in the exposed columnar epithelium, resulting in the development of metaplastic squamous epithelium. This area of transformation is termed the 'cervical transformation zone' (cervical TZ), and it is within this area that preneoplastic changes can occur with the development of CIN. It is thought that these dysplastic changes occur at the time of metaplasia, indicating that this is the time when the cervix is most vulnerable to potential carcinogenic factors, such as HPV and other cofactors.

These considerations have important clinical significance with regards to detecting and treating CIN, as these changes occur within the cervical TZ and it is accessible. Furthermore, the recognition that the development of precancerous changes can occur early in a woman's sexual and reproductive life provided some indication that these events were potentially associated with some form of environmental exposure related to sexual activity. In other words, most of the identified risk factors for CIN are thought to be largely surrogate markers of HPV infection (Table 38.1).

Malignant potential of cervical premalignant lesions

Cervical intraepithelial neoplasia

The malignant potential of CIN3 was shown by McIndoe et al (1984) in a crucial paper. This indicated that approxi-

Table 38.1 Risk factors for cervical intraepithelial neoplasia

- Early age at first intercourse (16 years or younger)
- History of multiple sexual partners
- Human papilloma virus infection, chlamydia or other sexually transmitted diseases
- Presence of other genital tract neoplasia
- History of previous cervical intraepithelial neoplasia
- Multiparity
- Cigarette smoking
- Combined oral contraception
- Dietary factors

mately 30% of women with CIN3 would develop invasive cancer over a 20-year period.

The authors' rationale for treating CIN3 is based upon this paper, which implies that when CIN3 is discovered, it should be treated. However, there are caveats. Firstly, the patients in this study had large carcinoma *in situ* lesions, and can we be sure that the undoubted premalignant potential for the lesions managed in this paper are shared by patients with smaller lesions that have small foci of CIN3? For example, it has been estimated that perhaps one-third of cases with CIN3 regress (Östör 1993).

Overall, it is thought that 1% of all CIN progresses to invasive cancer. Studies indicate that approximately 45–60% of CIN1 regress, 22–45% persist without progression and 10–16% progress to CIN3; whereas 28–40% of CIN2 regress, 20–40% persist and up to 50% progress to CIN3. However, all these studies are blighted by the difficulty in accurately determining the grade of the initial lesion and methodological variations.

These data indicate that treatment should always be considered for CIN3, but not necessarily for lesser grades of CIN. However, given the shortcomings in accurate assessment and the risk of progression of these cases, careful follow-up of untreated cases is mandatory.

Cervical glandular intraepithelial neoplasia

The relative rarity of this condition and classification problems have made this a more difficult area to study compared with squamous lesions. However, there is good evidence to support the concept that high-grade CGIN is a premalignant condition.

Aetiology of cervical premalignancy

The epidemiological risk factors for both squamous and glandular cervical premalignant lesions are similar and include young age at first intercourse and multiple sexual partners. It is now well established that infection with oncogenic high-risk HPV types is the central causal factor in the development of cervical neoplasia (Walboomers et al 1999).

The fact that virtually all cervical malignancies contain HPV DNA illustrates the central role of HPV in cervical carcinogenesis. It has now been proven beyond reasonable doubt that HPV infection is a necessary prerequisite for cervical carcinogenesis.

HPVs are small double-stranded DNA viruses which have an icosahedral protein capsid (Figure 38.4). They are typed according to the DNA sequence homology in particular

Figure 38.4 Model of human papilloma virus showing the arrangement of capsid proteins.

genes, specifically *L1* (which codes for the viral capsid) and *E6* and *E7* (which have important carcinogenic functions). Nearly 30 HPV types can infect the genital tract and can be classified into high-, intermediate- and low-risk oncogenic types. HPV types 16 and 18 are by far the most common high-risk types, accounting for 60% of HPV-positive invasive cervical cancers.

HPV infection can lead to integration of viral DNA into the host's genome, with expression of the viral oncogenes *E6* and *E7* which produce proteins that interfere with tumour-suppression genes controlling the cell cycle. As a result, the cell loses the ability to repair DNA damage and to undergo apoptosis, becoming susceptible to additional mutations and genomic instability. It is therefore postulated that HPV integration can lead to carcinogenesis.

HPV infection is very common. It can be detected in up to 20% of sexually active women in the reproductive age group, and approximately 80% of women will, at some point, be infected. In most cases, genital HPV infections are transient with only a small proportion developing persistent infection, but the risk of subsequent development of CIN increases substantially in this group. HPV alone is not thought to lead to neoplastic change, and other cofactors are thought to be involved, such as smoking-related carcinogens, and dietary and hormonal factors.

Prevention of cervical premalignancy

The recognition that risk factors for cervical neoplasia were sexually related suggested the potential for a number of primary preventive strategies.

Primary prevention using behavioural changes

An obvious strategy was modification of sexual behaviour. Options included the use of sexual health education, particu-

larly advocating the use of barrier methods of contraception which are associated with a reduced incidence of CIN. Smoking is another consideration. Reducing or quitting smoking is associated with improvements in CIN. Nonetheless, the potential of these approaches is limited by the reality of only limited success in persistently changing human behaviour.

Primary prevention using immunization

Recognition of the central role of HPV in the pathogenesis of cervical neoplasia suggested that primary prevention was possible through the development of prophylactic HPV vaccines. These have been shown to be highly immunogenic, to generate high levels of neutralizing immunoglobulin G antibodies, and to persist for at least 5 years. Antibody responses are higher around the time of puberty (9–15 years), indicating that this should be the target population. What is not known is how long the duration of protection lasts, and whether or not booster immunization is needed.

Several phase III trials (Ault 2007) have shown that more than 90% of persistent HPV 16/18 infections can be prevented for up to 5 years after vaccination, and that more than 90% of precancerous lesions can be prevented in subjects who were HPV negative prior to vaccination. The long-term effects on cervical cancer incidence will require another 10–20 years of follow-up.

The optimal target age for prophylactic vaccination is just before the start of sexual activity (i.e. 9–14 years), as HPV infection may occur soon afterwards. The UK HPV vaccination programme began in 2007. Girls in Year 8 at school (aged 12–13 years) are offered a bivalent HPV vaccine (Cervarix) which protects against infection with HPV 16/18 types. The programme involves three injections over 6 months.

Women will still develop cervical cancer despite HPV vaccination. It is estimated that 70% of cervical cancers might be prevented by HPV vaccination, so primary cervical screening will still be needed, albeit in a modified version.

Detection of cervical premalignancy

Population-based screening should be conducted using well-organized and high-quality programmes with high coverage, as well as providing adequate treatment for detected lesions.

In the developed world, cervical cytology has formed the basis of screening programmes, but the resources and infrastructure required have precluded its use in poorer countries. Current debate concerns the use of the HPV detection assay as a screening tool, whereas in poorer countries, attention has focused on cheaper screening techniques that involve visually assessing the cervix, such as cervicography and visual inspection with acetic acid.

Cervical cytology

The recognition that cervical cytology could be used to detect precancerous change led to the introduction of cervical cytology as a screening test (Figure 38.5). Early detection and treatment can prevent the development of 75% of cancers. Whilst cytology is used to detect women at risk of having cervical premalignancy, most abnormalities are not precancerous. Only a small proportion of women with abnormal

Figure 38.5 (A) Dyskaryotic squamous cells showing mild and moderate dyskaryosis. There is cytoplasmic clearing resulting in a clear area around the nucleus indicative of koilocytosis, which is a papilloma-virus-related cytopathic change (Sure Path, original magnification $\times 60$). smears would develop cancer, although these women are high risk compared with the normal population. There is therefore huge potential for overtreatment unless one can accurately select which lesions require treatment.

In the UK, the incidence of cervical cancers has halved since the National Health Service's (NHS) cervical screening programme was introduced in 1988. The NHS cervical screening programme is highly organized. In the UK, women aged 25–65 years are invited for screening every 3 or 5 years. It is thought that screening under the age of 25 years may do more harm than good as cervical cancer is rare in this age group (Sasieni and Adams 1999). There are clear service guidelines, effective data collection systems using a number of mandatory returns from cytological laboratories, and internal and external quality assurance systems. Target population coverage is the key to success. The programme aims for coverage of over 80% of the target population, but there has been a worrying fall in levels in recent years, falling as low as 66% in women aged 25–30 years (Figure 38.6).

In spite of the success achieved by cervical cytology, it is not without its shortcomings. The assessment and definition of cytological abnormality are subjective with considerable

interobserver variation. The process is laborious and tiring with considerable scope for operator error, especially when the workload is high. Furthermore, cytology screening has little effect on the incidence of adenocarcinoma of the cervix.

False-negative results have been variously estimated as being between 2.4% and 26% in various types of study. False-negative results can occur because of inadequate sampling, incorrect laboratory processing, or detection and interpretative errors of the cell samples. This type of error is potentially serious, as a falsely reassuring result may result in no further investigation for 3–5 years, but it is relatively uncommon. There is a need for less labour-intensive and more reliable screening methods.

HPV detection assay

Up to 20% of women, depending on their age, will have evidence of HPV infection using sensitive techniques, such as hybrid capture 2. These assays have high sensitivity but poor specificity, making this a poor test for identifying women with CIN, although specificity rises with age. However, the negative predictive value of these assays is high, making them useful as a means of identifying women who do not have CIN.

It is likely that the combination of prophylactic HPV vaccination and the use of HPV testing as a primary test will be the most cost-effective strategy. Assuming a protective effect of prophylactic HPV vaccination of 15–20 years, nationwide prepubertal vaccination may allow delaying the onset of the cervical screening programme to 30 years instead of 25 years as is the current guidance (Bulkman et al 2007).

Colposcopy

Colposcopy should not be regarded as an effective primary screening tool, but is essential for diagnosing and treating premalignant lesions detected by either cytology or HPV testing.

Colposcopy involves the visual examination of the cervix under magnification and with enhancement from dilute acetic acid. It is usually performed in women with abnormal smears or an abnormal-looking cervix. It aims to detect macroscopic changes in tissue features such as colour and morphology which are used to classify the lesion.

Colposcopy aims primarily to examine the whole of the cervical TZ, extending from its innermost margin at the SCJ to the outer margin where the metaplastic squamous epithelium adjoins native squamous epithelium.

Colposcopic examination

Women are examined in a modified lithotomy position, often using a colposcopy couch which facilitates easy adjustment of height and position. A bivalve speculum is then introduced and the cervix visualized.

At the initial examination, obvious macroscopic abnormality is sought, including leukoplakia, viral condylomata and invasion. Invasion is associated with the surface of the cervix appearing raised or ulcerated (Figure 38.7). Atypical vessels seen on invasive lesions run a bizarre course and are often corkscrew- or comma-shaped (Figure 38.8). Condylomata are usually obvious from their regular frond-like surface (Figure 38.9).

Having completed the initial inspection of the cervix, 5% acetic acid is applied liberally and gently. This turns abnormal epithelium white, producing the so-called 'acetowhite' changes of CIN. The position of the SCJ must then be ascertained to define the upper limits of the abnormality. On the basis of these findings, the cervical TZ can be classified into one of three types (Figure 38.10). In a type III TZ, the SCJ is not visible and the examination cannot be regarded as satisfactory. This has important management implications.

Colposcopic abnormalities

The key colposcopic features of suspected abnormalities are acetowhitening, abnormal vasculature and topography.

Acetowhite change is the most important of all colposcopic features. Its actual mechanism is uncertain, but it is a reversible reaction which has an association with the activity of the epithelium and results in a temporarily increased reflection of light (Figure 38.11). These changes are non-specific. There is a spectrum of change from low- to high-density acetowhitening which corresponds with an increasing likelihood of high-grade CIN.

Abnormal vascular patterns comprise punctuation, mosaicism (Figure 38.12) and abnormal vessels. In general terms, the coarser the vascular pattern, the greater the likelihood of high-grade change. Abnormal vessels are typically irregular in size, shape and arrangement, and can suggest the presence of invasion.

CIN is usually a distinct acetowhite lesion with sharp margins. It often shows a mosaic vascular pattern with

patches of acetowhite separated by vessels like red weeds between white flagstones. Where the vessels run perpendicular to the surface, punctuation is seen as the vessels are viewed end-on. This appears as red spots on a white background. In general, the more quickly and strongly the acetowhite changes develop, the clearer and more regular the margins of the lesion, and the more pronounced the mosaic or punctuation, the more severe the lesion is likely to be.

Colposcopic diagnosis

Colposcopic diagnosis is multifaceted. In part, it involves comparing the visual findings with the established patterns of disease as described above. These skills and abilities require training and experience. In addition, there are other important factors that a colposcopist uses to make a diagnostic decision, and these include the referring cytology, patient's age and parity, and smoking history. These other factors are, on occasions, at least as important as the colposcopic image in making a diagnosis, especially when the colposcopic features are low grade or normal. This observation has led to the use of a number of scoring systems to facilitate diagnosis (Table 38.2), although these are not recommended for routine clinical use.

Colposcopy is not reliable when the SCJ cannot be seen, when glandular lesions are suspected, and when there has been previous treatment. In these circumstances, if a high-grade lesion is suspected, an excisional biopsy of the cervix should be performed.

As with any subjective test, a high variation in colposcopic performance has been reported in terms of specificity, sensitivity, and inter- and intraobserver variability. The sensitiv-

Figure 38.11 Tissue basis for colposcopy. (A) Normal epithelium, (B) abnormal (atypical) epithelium.

Source: Singer A, Monaghan J 2000. *Lower Genital Tract Precancer*. Blackwell Science, Oxford, p 10.

ity of colposcopy to distinguish normal from abnormal tissue is relatively high, but it is less good at differentiating low-grade lesions from high-grade lesions. The sensitivity of colposcopy for detecting high-grade disease is approximately 50%. Women undergoing colposcopy are therefore at risk from both overtreatment and underdiagnosis.

Colposcopic diagnostic performance might be improved using some technological innovations such as digital image enhancement (Figure 38.13), and reflective and impedance spectroscopy (Louwers et al 2008). Despite a number of promising initial reports, these newer techniques have not been adopted, principally because of expense, inconvenience and insufficient high-quality evidence.

Table 38.2 Clinicocolposcopic index

Variable	Score		
	Zero points	One point	Two points
Index cytology	Low grade	—	High grade
Smoking	No	—	Yes
Age (years)	≤30	>30	—
Acetowhitening	Slight	Marked	—
Surface area (cm ²)	≤1	>1	—
Interpapillary distance (μm)	≤350 (fine or no mosaic/punctuation)	>350 (coarse mosaic/punctuation)	—
Focality of lesion	Unifocal or multifocal	Annular	—
Surface pattern	Smooth	Irregular	—

Source: Shafi MJ, Nazeer S: 2006 Colposcopy — A Practical Guide. Fivepin Publishers, Salisbury.

For each individual patient, a maximum score of 10 can be achieved. The higher the score, the more significant the lesion: score of 0–2, insignificant lesions; score of 3–5, low-grade lesions; score 6–10, high-grade lesions.

Colposcopic biopsy

Colposcopy is often viewed as a means of deciding whether or not to take a biopsy and where to take it from. Colposcopic biopsies can be classified as in Figure 38.14. An extended excisional biopsy aims to sample most of the endocervical canal and can be performed when the SCJ is not visible or a glandular lesion is suspected. It is accepted that excisional biopsy is the gold standard for histological diagnosis, but this is best avoided when low-grade lesions are suspected.

The colposcopically-directed punch biopsy (CDB) is often used, but the reliability and validity of this test is question-

Figure 38.13 Dynamic Spectral Imaging System (DySIS; Forth Phototonics, Athens, Greece) is a colposcope that measures the acetowhitening of every image pixel of the cervix after the application of acetic acid.

Figure 38.14 Classification of cervical biopsies.

able for a variety of reasons. Few studies have been performed that have assessed the reliability of CDB, and these have been of poor quality. CDB should be avoided when the TZ cannot be fully seen, or when glandular lesions or high-grade lesions are suspected. If CDB is to be used, multiple biopsies must be taken.

Treatment of cervical premalignancy

Effective treatment involves striking a balance between the risks of persistent and recurrent disease from undertreatment and excessive damage due to overtreatment. This is particularly pertinent in the management of cervical precancerous change, as many women undergoing treatment will not have started or completed their child bearing.

A failure to appreciate the nature and behaviour of cervical premalignancy has bedevilled its treatment. In the past, CIN was treated by radical hysterectomy but it soon became evident that this was unnecessary, and simple hysterectomy became the method of choice. In time, it was realized that cone biopsy was just as effective, and hysterectomy is now reserved for women with difficult-to-treat recurrent disease or who have additional indications for hysterectomy. The introduction of colposcopy and a better appreciation of the limited location of CIN led to the introduction of more conservative methods of treatment (Soutter and Fletcher 1994).

There is no doubt that high-grade CIN (CIN2/3) and high-grade CGIN should be treated, but there is uncertainty about the therapeutic value of treating CIN1. Whilst conservative treatment is increasingly adopted, follow-up should be performed until spontaneous regression or treatment is performed.

The treatment morbidity is a function of the amount of tissue removed or destroyed. The potential complications are:

- intraoperative haemorrhage;
- secondary haemorrhage;
- pelvic infection;
- cervical stenosis; and
- cervical incompetence.

With the exception of radical diathermy, ablative treatments were not associated with a significantly increased risk of serious adverse pregnancy outcomes. However, all excisional procedures used to treat CIN seem to be associated with adverse obstetric morbidity, but among these, only cold knife conization is associated with a significantly increased rate of severe outcomes (Kyrgiou et al 2006). The risk of serious obstetric morbidity has not been confirmed with the use of loop excision, but excisions that remove large amounts of cervical tissue probably have the same effect as knife cone biopsies. Most loop excisions in young women with fully visible transformation zones only need to be 1 cm deep, and this should protect against serious obstetric outcomes.

Types of treatment

Ablation

A number of ablative methods are available (Table 38.3). The potential advantages of ablative treatments are that general anaesthesia is not usually required (with the exception of radical electrodiathermy) and the associated damage

Table 38.3 Treatment for cervical intraepithelial neoplasia

	Method	Anaesthesia	Obstetric morbidity*
Ablation	Radical electrodiathermy	GA	++
	Laser vaporization	LA	+/-
	'Cold' coagulation	LA	+/-
Excision	LLETZ	LA	+/-
	NETZ	LA	+/-
	Laser conization	LA	+
	Knife conization	GA	++
	Hysterectomy	GA	+++

*Based on Arbyn M, et al 2008 Perinatal mortality and other severe adverse pregnancy outcomes associated with treatment of cervical intraepithelial neoplasia: meta-analysis. *BMJ* 337: a1284.

GA, general anaesthesia; LA, local anaesthesia; LLETZ, large loop excision of the transformation zone; NETZ, needle excision of the transformation zone.

Table 38.4 Contraindications for ablative treatment

- Suspected invasive disease
- Suspected glandular disease
- Squamocolumnar junction not clearly visible
- Previous cervical surgery, including cryocautery
- Unexplained cytological abnormality, i.e. significant smear/colposcopy discrepancy

might be less. This might mean less obstetric morbidity. However, there are caveats. Firstly, the treatment method has to be fit for purpose; cryotherapy, for example, is easy to use but it destroys insufficient tissue to treat CIN adequately.

Secondly, ablative therapy can only be undertaken when the whole of the cervical TZ can be examined reliably, so the SCJ must be visible. When ablative treatment is contraindicated (Table 38.4), excisional therapy must be performed.

Finally, a disadvantage common to all these techniques is that they depend upon the exclusion of invasion by colposcopy and directed biopsy, which is not necessarily sufficiently reliable. Furthermore, as the treated tissue is destroyed, it is not possible to know for certain what has been treated and whether it has been treated adequately.

Excision

Excisional treatments range from local treatments to hysterectomy (Table 38.3). The extent of local excision depends on the context. When treating ectocervical lesions, the aim is to excise to a depth of approximately 10 mm. However, the depth of excision may need to be extended if the SCJ is not visible or if a glandular lesion is suspected.

When high-grade CGIN is suspected and conservative treatment is preferred, local excision is appropriate provided that the lesion is excised completely. When the margins are not free of disease, a simple hysterectomy is probably the safest treatment, provided that invasive disease has been excluded. A further cone biopsy as definitive treatment

would be acceptable management for young women who want more children. If the margins are clear, close observation with 6-monthly cervical smears is reasonable management provided that both patient and physician are aware of the relatively high likelihood of the need for further treatment for suspected recurrence.

The principle advantage of excisional treatments is that there is histological confirmation of what has been treated and whether or not excision is complete. Compared with ablative treatments, there might be greater scope for damage but that is a function of the amount of tissue removed.

Large loop excision of the transformation zone (LLETZ) is the most common method. It is simple and easy to use on an outpatient basis, usually only requiring local analgesia. The amount of tissue removed and the shape of the sample is largely predetermined by the shape and size of the loop. Wherever possible, the specimen should be removed as a single specimen. Unfortunately, larger lesions (i.e. those at greatest risk of being high grade and incompletely excised) are often removed in multiple fragments, making orientation of the specimen and assessment of the completeness of excision impossible.

Knife cone biopsy still has utility when larger specimens are needed or when greater histological certainty of excision status is required. However, this requires general anaesthesia.

Choice of treatment

None of the methods of treating CIN are more effective than any of the others when used appropriately by a well-trained and experienced operator. Each has particular advantages with regards to cost, ease of use, speed or precision. The particular method chosen will depend upon local circumstances. It seems sensible to choose a method which will allow abnormalities to be treated under local anaesthesia. In spite of its greater capital cost, the laser does have the advantage that it can be used to excise and vaporize lesions when it is appropriate to do so. However, needle excision of the TZ and LLETZ have largely replaced the laser because of the reduced capital cost, greater simplicity in maintenance of the instrument, and more rapid treatment with less blood loss.

Results of treatment

Treated adequately, some 5% of patients treated for CIN will have recurrent disease within 2 years. Thereafter, the number of recurrences is small. However, long-term follow-up is necessary as these women remain at higher risk of CIN or invasive cervical cancer than the general population. Currently, it is recommended that patients treated for high-grade CIN should have increased cytological surveillance for 10 years.

The Vagina

Terminology and pathology of vaginal intraepithelial neoplasia

The terminology and pathology of vaginal intraepithelial neoplasia (VAIN) is analogous to that of CIN (VAIN1–3).

The main difference is that vaginal epithelium does not normally have crypts so the epithelial abnormality remains superficial until invasion occurs. The common exception to this is found following surgery (usually hysterectomy) when abnormal epithelium can be buried below the suture line or in suture tracks.

Natural history of vaginal intraepithelial neoplasia

VAIN is seldom seen as an isolated vaginal lesion. It is more usual for it to be coexistent with CIN. In most cases, it is diagnosed colposcopically prior to any treatment during the investigation of an abnormal smear. However, it may not be recognized until after a hysterectomy has been performed. When this happens, abnormal epithelium is likely to be buried behind the sutures used to close the vault and cannot be assessed (Figure 38.15). Untreated or inadequately treated VAIN may progress to frank invasive cancer. Very rarely, VAIN may be seen many years after radiotherapy for cervical carcinoma, when it is probably a new lesion. Care must be taken in these women to ensure that postradiotherapy changes are not being misinterpreted as VAIN.

Assessment of vaginal intraepithelial neoplasia

VAIN is often detected by abnormal cytology following hysterectomy. Colposcopy of the vagina is more difficult than that of the cervix, particularly if the patient has had a hysterectomy, as it is very difficult to see into the angles of the vagina, and impossible to visualize epithelium that lies above the suture line or vaginal adhesions. The colposcopic features of VAIN are very similar to those of CIN, except that mosaic is seen less often. Punch biopsy can indicate whether or not there is an abnormality, but assessment short of complete excision must be regarded as suboptimal.

Figure 38.15 Sutures in the vaginal vault isolate a cuff of the vagina above the suture line.

Treatment of vaginal intraepithelial neoplasia

As with the cervix, excision avoids suboptimal assessment and inadvertent inadequate management of invasive lesions. Ablative treatments appeal because of their apparent simplicity, but they can be associated with morbidity as well as compounding the dangers of undertreatment with future difficulties in assessment.

In the past, a number of ablative techniques such as carbon dioxide laser, topical 5-fluorouracil and radiotherapy have been used, but surgical excision gives better results and is the only effective option available to patients previously treated with radiotherapy. Following hysterectomy, an abdominal or combined abdominal and vaginal approach is preferable to vaginal excision (Ireland and Monaghan 1988).

The Vulva

Vulvar intraepithelial neoplasia (VIN) is seen more commonly than was the case 10–20 years ago. It is not certain whether this represents a real increase or is simply the result of a greater awareness of the problem.

Pathology of premalignant disease of the vulva

Premalignant squamous lesions of the vulva are labelled 'vulvar intraepithelial neoplasia' (VIN). This term has been adopted by the International Society for the Study of Vulvar Disease and the International Society for Gynecologic Pathologists. This replaces previous terminology such as 'hyperplastic dystrophy', 'Bowen's disease', 'squamous dysplasia' and 'carcinoma *in situ*'.

VIN is classified into two distinct clinicopathological subtypes: classic (Bowenoid, usual type) and simplex (differentiated). Classic VIN is seen in younger women and is associated with HPV. Multifocal involvement of the vulva occurs in more than 40% of cases, and multicentric involvement affecting the vagina, cervix and perianal region occurs in 18–52% of patients. Approximately 50% of women with VIN present with symptoms of pruritus, irritation or a mass lesion, and in the remainder it is an incidental finding. Local recurrence or persistence has been noted in 7–32% of patients following therapy. Occult areas of invasive carcinoma are seen in approximately 6–18% of patients treated surgically for VIN. Histologically, classic VIN may have a warty pattern with an undulating surface, and frequent koilocytosis or multinucleation or a basaloid pattern with a relatively flat lesion where the normal epithelium is replaced by a fairly homogeneous proliferation of abnormal cells. Both types can coexist. Classic VIN is graded depending on the level of involvement of the affected epithelium by abnormal cells. This grading scheme is similar to that used in CIN: VIN1, when the lowest third is involved; VIN2, when the lower two-thirds are involved; and VIN3, when the abnormality extends to the upper third of epithelium. VIN1 is uncommon.

Simplex (differentiated) VIN is much less common and accounts for less than 10% of VIN cases. It occurs in postmenopausal women and is associated with lichen sclerosis. HPV is uncommon with differentiated VIN; however, it has

a strong association with vulvar squamous cell carcinoma. Histologically, simplex VIN is a subtle lesion with a generally well-preserved architecture, thickened epidermis, abnormal basal keratinocytes and deeply situated abnormal individual cell keratinization.

Vulvar Paget's disease is said to represent adenocarcinoma *in situ* and is very rare. The histological appearance of Paget's disease is similar to the lesion seen in the breast. In one-third of cases of Paget's disease, there is an associated invasive cancer, often an adenocarcinoma, in underlying apocrine glands and these carry an especially poor prognosis.

Natural history of vulvar intraepithelial neoplasia

Forty per cent of women with VIN are under 41 years of age. Although histologically very similar to CIN and often occurring in association with it, VIN does not seem to have the same malignant potential. However, this opinion is based largely on studies of women who have been treated by excision biopsy or vulvectomy.

Diagnosis and assessment of vulvar intraepithelial neoplasia

VIN often presents with itching, but 20–45% are asymptomatic and are frequently found after treatment of preinvasive or invasive disease at other sites in the lower genital tract, particularly the cervix.

These lesions are often raised above the surrounding skin and have a rough surface. The colour is variable: white, due to hyperkeratinization; red, due to thinness of the epithelium; or dark brown, due to increased melanin deposition in the epithelial cells. They are very often multifocal.

Adequate biopsies must be taken from abnormal areas to rule out invasive disease. This can usually be done under local anaesthesia in the outpatient clinic using a disposable 4-mm Stiefel biopsy punch or a Keyes punch.

Treatment of vulvar intraepithelial neoplasia

Treatment of VIN is difficult. Uncertainty about the malignant potential, the multifocal nature of the disorder, and the discomfort and mutilation resulting from therapy suggest that recommendations should be cautious and conservative in order to avoid making the treatment worse than the disease. The youth of many of these patients is a further important consideration. In view of the mutilating nature of treatment, the high recurrence rate and the uncertainty about the risk of invasion, there is a place for careful observation, especially of young women without severe symptoms.

The documented progression of untreated cases of VIN3 to invasive cancer underlines the potential importance of these lesions. If the patient has presented with symptoms, therapy is required. Asymptomatic patients, particularly those under 50 years of age, may be observed closely with biopsies repeated if there are any suspicious changes.

Medical therapy

The main role for medical treatment is in relieving symptoms in women for whom surgery may be avoided.

Provided invasion has been excluded as far as possible, topical steroids provide symptomatic relief for many women. A strong, fluorinated steroid is usually required. This may be applied twice daily for not more than 6 months because of the thinning of the skin which can result. Frequent review is necessary initially.

Surgery

If the lesion is small, an excision biopsy may be both diagnostic and therapeutic. If the disease is multifocal or covers a wide area, wider excision may require plastic surgery using split skin grafting or transpositional skin flaps.

Assessment of the results of treatment should include consideration of the length of follow-up. Surgical excision is associated with crude recurrence rates of 15–43%.

Carbon dioxide laser

An alternative approach is to vaporize the abnormal epithelium with a carbon dioxide laser. Careful control of the depth of destruction is essential for good cosmetic results. Given the very irregular surface of the vulva, it is very difficult to achieve a uniform depth of destruction. Moreover, the depth of treatment required for VIN is still unclear. In some cases, hair follicles may be involved for several millimetres below the surface, but it may not always be necessary to destroy the whole depth of involved appendages. In any case, treatment of the whole vulva to such a depth would result in a third-degree burn which would need skin grafting. In practice, laser vaporization has proved to be disappointing in UK practice and is seldom used (Shafi et al 1989).

Paget's disease

This is an uncommon condition and is similar to that found in the breast. It is characterized by large malignant cells arranged singly and in clusters. The typical Paget's cell has a vesicular nucleus and abundant cytoplasm which contains demonstrable mucin (Figure 38.16). The cells of primary Paget's disease are characteristically positive with cytokeratin 7, carcinoembryonic antigen, CAM 5.2, androgen receptor, gross cystic disease fluid protein 15 and human epidermal growth factor receptor 2 (HER 2) (Goldblum and Hart 1997).

The disease is often extensive or multifocal, so clinically unsuspected positive resection margins are not uncommon. No underlying regional malignancy is identified in the majority of cases, but up to 30% of cases have invasion of the dermis, microscopically noted but often clinically unsuspected. The main differential diagnosis of Paget's disease is superficial spreading malignant melanoma which will, in contrast to Paget's disease, show positivity for S100, HMB45 and Melan A. Concomitant genital malignancies are found in 15–25% of women with Paget's disease of the vulva; these are most commonly vulval or cervical, but transitional cell carcinoma of the bladder (or kidney), and ovarian, endometrial, vaginal and urethral carcinomas have all been reported.

Pruritis is the presenting complaint and it often presents as a red, crusted plaque with sharp edges (Figure 38.17), sometimes with multiple erosions. The diagnosis is made histologically on biopsy.

Figure 38.16 Single and nested Paget cells showing characteristic abundant cytoplasm and vesicular nuclei (block arrow). The inset shows the cells highlighted by cytoplasmic and membranous staining with cytokeratin 7 (arrowed). Original magnification x100.

The treatment of Paget's disease is very wide local excision, usually involving total vulvectomy because of the propensity of this condition to involve apparently normal skin. The specimen must be examined histologically with great care to exclude an apocrine adenocarcinoma.

The Uterine Corpus

Introduction

The concept of premalignancy in the uterine corpus is confined to the endometrium. Myometrial neoplasms, such as leiomyomas, leiomyosarcomas and endometrial stromal sarcomas, do not have a recognized preneoplastic phase.

Terminology of endometrial premalignancy

Endometrial carcinoma is the most common malignancy of the female genital tract in the Western world. Simplistically and conceptually, there are two types of endometrial carcinomas: type 1, oestrogen-related, endometrioid carcinoma; and type 2, non-oestrogen-related, prototypically serous carcinomas. Type 1 carcinoma is more common and has a precursor termed 'endometrial hyperplasia'. Endometrial hyperplasia is best described as a non-physiological, non-invasive proliferation of glands visibly resulting in an increase in the volume of endometrial glands relative to the stroma. The precursor of type 2 carcinoma is termed 'endometrial intraepithelial carcinoma' (EIC).

The World Health Organization (WHO) classification of endometrial hyperplasia is into simple and complex hyperplasia. Both simple and complex hyperplasia can be associated with cellular atypia. Simple atypical hyperplasia is exceedingly rare. Complex atypical hyperplasia is

Figure 38.17 Paget's disease of the vulva. Note the crusted surface and clear margins.

commonly termed 'atypical hyperplasia', and is closely related to progression or coexistence of endometrial carcinoma. In women who undergo hysterectomy soon after a biopsy that shows atypical hyperplasia, the uterus shows an established endometrioid adenocarcinoma in 17–45% of cases in various series reported in the literature. When such a cancer is discovered, it is almost always a low-grade, low-stage carcinoma.

Histopathology of endometrial premalignancy

On histopathological examination, all forms of hyperplasia show an increase in the number of glands in comparison with the stroma. Simple and complex forms of hyperplasia are distinguished by the gland morphology. Simple hyperplasia is characterized by variably sized cystically dilated glands. The stroma is abundant relative to the lesser volumes of stroma seen in complex hyperplasia. The latter shows more densely crowded glands with irregular outlines, and outpouching and infoldings of the lumen. The glands are closely packed, although stroma is consistently identified between the glands. In any sample of endometrium, a combination of simple and complex hyperplasia may be seen. Cellular atypia is identified by nuclear enlargement, rounded outlines and irregularity of nuclear chromatin.

The diagnosis of endometrial hyperplasia has been shown in several studies to be an area of gynaecological pathology with low diagnostic reproducibility. Even after accounting for extrinsic factors such as scanty sample or low volume changes, there is disagreement amongst general and specialist pathologists in the diagnosis of complex hyperplasia and cytological atypia. These difficulties in reproducibility of diagnosis are likely to be secondary to lack of strict definition and objective criteria in the present WHO clas-

sification. There is a proposal from Mutter and colleagues from Boston to use more specific diagnostic criteria for precancerous changes in the endometrium termed 'endometrial intraepithelial neoplasia'. This classification is currently under discussion and has not replaced the current WHO classification.

EIC represents the precursor lesion of type 2 endometrial carcinoma. This lesion occurs in a background of atrophic endometrium, and has cells with pleomorphic nuclei that are immunoreactive for *p53*. By definition, EIC does not show myometrial invasion. Biologically, however, EIC can be aggressive with extrauterine spread noted at the time of diagnosis. This diagnosis of EIC can trigger management as carcinoma.

Aetiology and molecular pathology of endometrial premalignancy

Type 1 endometrial carcinoma is associated with hyperoestrinism. The development of endometrial hyperplasia is strongly influenced by steroid hormones; oestrogen induces glandular proliferation leading to thickening of the uterine lining, whereas growth is suppressed by progesterone. This is reflected by the risk factors for endometrial hyperplasia, including obesity, nulliparity and oestrogen-only hormone replacement therapy, which are associated with states of prolonged unopposed oestrogen. Hyperoestrogenic states such as polycystic ovary syndrome have a greater incidence of endometrial hyperplasia, as do patients taking the partial oestrogen agonist tamoxifen for breast cancer. Although there is no association with hyperoestrinism, hereditary non-polyposis colonic cancer is known to have an increased incidence of hyperplasia.

The most frequently altered gene in type 1 carcinoma is *PTEN*, located on chromosome 10. Up to 55% of preneoplastic lesions reveal loss of *PTEN* expression. This loss of *PTEN* is an early event in endometrial tumorigenesis. Mutations of *p53* are found in approximately 80% of precursors of type 2 carcinoma.

Screening for endometrial premalignancy

Endometrial hyperplasia is typically diagnosed in perimenopausal women. There are few data in the literature regarding screening of asymptomatic women for endometrial hyperplasia. Both ultrasonography for endometrial thickness and outpatient endometrial biopsy have yields too low to justify investigation of asymptomatic women.

Clinical presentation of endometrial hyperplasia

Endometrial hyperplasia usually presents with abnormal uterine bleeding. This includes menorrhagia, intermenstrual bleeding, postcoital bleeding and postmenopausal bleeding. Occasionally, endometrial hyperplasia might be detected in asymptomatic women being investigated for smears containing atypical endometrial cells. Endometrial hyperplasia can occur in both pre- and postmenopausal women, accounting for approximately 15% of women presenting with postmenopausal bleeding.

Investigation of endometrial hyperplasia

In the UK, the cancer waiting time and 18-week waiting time initiatives have increasingly focused attention on one-stop assessment and diagnosis. Women over the age of 45 years with irregular bleeding or postmenopausal women are referred on the cancer pathway and seen within 14 days. Transvaginal ultrasound (TVS) is the primary investigation of choice in postmenopausal women as it can assess the endometrium and detect other relevant pelvic pathologies. The endometrial thickness is measured and, using a cut-off of more than 5 mm, has a high sensitivity and specificity for detecting endometrial pathology, as well as a true negative predictive value approaching 100% (Smith-Bindman et al 1998). If the endometrial thickness exceeds 5 mm, endometrial assessment is required. Whilst the diagnostic gold standard is hysteroscopy, blind endometrial sampling using tests such as Pipelle (Punimar, Wilton, Connecticut, USA) are frequently used and are cost-effective. When outpatient sampling is not feasible or is unsatisfactory, or in the context of the patient being on tamoxifen or in whom symptoms have persisted despite negative findings on initial assessment, hysteroscopy should be undertaken. Hysteroscopy allows the whole surface of the uterine cavity to be inspected and facilitates targeted biopsy or curettage. Hysteroscopy with biopsy has an excellent sensitivity and specificity for detecting endometrial pathology in women aged less than 45 years who have symptoms of irregular and/or heavy bleeding that is non-responsive to first-line management. In this clinical scenario, an endometrial sample should be the primary test, as TVS is less specific. Notwithstanding the above, TVS should always be considered when clinical findings are abnormal or examination is suboptimal.

Management of endometrial hyperplasia

The management will depend upon the nature of the abnormality and upon the patient's wishes for further children. As most types of endometrial hyperplasia do not progress to endometrial cancer, treatment regimens should be individualized; hysterectomy is unnecessary in the majority of cases. On the other hand, the presence of cytological atypia with its risk of concomitant cancer or risk of progressing to endometrial cancer should be managed as if cancer was there, unless there are powerful considerations to do otherwise, such as fertility issues or significant medical comorbidity.

Non-atypical endometrial hyperplasia (simple or complex hyperplasia)

Given the low risk of progression to carcinoma, there is no indication for hysterectomy or for progestin therapy in asymptomatic women, and subsequent management can probably be decided on the basis of further symptoms. Available data suggest that persistent or progressive disease will occur in one-third of conservatively managed cases (Clark et al 2006). Progestin therapy may result in its complete disappearance. Progestogens can be delivered systemically, either alone or in combination with oestrogen (as in the oral contraceptive pill or hormone replacement therapy),

or locally in the form of the levonorgestrel intrauterine device (Mirena, Schering Health). Both systemic and local administration of progestogens show a 75–100% conversion rate to normal endometrium.

Atypical hyperplasia

Most women with atypical hyperplasia should have a hysterectomy and bilateral salpingo-oophorectomy because of the high risk of coexistent carcinoma. However, younger women who wish to preserve their fertility may be managed with medical therapy and repeated endometrial sampling. One study reported a 94% success rate with 3–18 months of therapy, allowing five women to become pregnant, delivering at full term (Randall and Kurman 1997). However, these encouraging results have to be weighed against those where a 25% risk of progression to carcinoma was described (Ferency and Gelfand 1989). Most data relate to the use of various progestins given for short-term courses or as continuous therapy for many years. Most of the studies only include carefully selected cases, and the results of the different studies are not really comparable because of the selection criteria applied. It is clear that these results should be regarded with considerable caution, and that long-term follow-up is essential because recurrences may not appear for many years (Ferency and Gelfand 1989).

The Ovary

Introduction

Ovarian cancer is a heterogeneous disease including epithelial neoplasms, germ cell and stromal tumours, and metastatic malignancies. The concept of ovarian premalignant disease is currently confined to epithelial neoplasms; however, its clinical usefulness has been limited by the diverse histological subtypes and the lack of an obvious precursor.

As a result, attention has focused on the detection of small early-stage cancers in certain situations, such as the need for careful examination of ovaries and fallopian tubes removed at prophylactic surgery in patients with *BRCA1* or *BRCA2* mutations since small areas of malignant change can easily be missed. Similarly, it is recognized that endometriosis can be coexistent in up to 25–40% of cases of endometrioid and clear cell ovarian cancers (Fukunaga et al 1997), and consequently all endometriotic cysts must be sampled optimally, especially to include any solid or suspicious areas. Only a small percentage of women with endometriosis will develop an ovarian cancer, and the mechanisms responsible for the malignant transformation have still to be elucidated. However, evidence is emerging of genetic mutations common to both ovarian endometriosis and endometriosis-associated ovarian cancer (Prowse et al 2006).

Ovarian carcinogenesis

Based on morphological and molecular genetic studies, a dualistic model has been suggested (Shih and Kurman 2004) in which ovarian cancers can be divided into two broad categories: type I and II tumours (Figure 38.18). The type I pathway resembles the adenoma–carcinoma pathway in

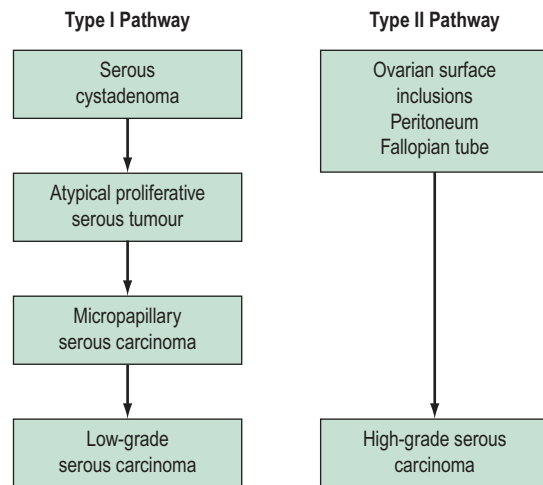

Figure 38.18 The dualistic model of ovarian cancer pathogenesis.
Adapted from Kurman RJ, Shih IM 2008 *International Journal of Gynecological Pathology* 27: 151–160.

colorectal cancer and is characterized by clearly recognized precursor lesions, namely cystadenoma and borderline lesions. Type I tumours evolve slowly in a stepwise fashion and are associated with distinct molecular changes that are not shared by the more common type II tumours. Type II tumours comprise high-grade tumours, such as poorly differentiated serous lesions and mixed mesodermal tumours, which arise and metastasize early.

The pathological evidence for the progression of type I tumours arises from studies which have shown the frequent occurrence of a transition or coexistence between malignant and benign areas in mucinous ovarian cancers, and between low-grade serous cancers and areas of borderline change (Malpica et al 2004). Also, borderline serous tumours typically recur as low-grade serous cancers (Crispens et al 2002).

The significance of this dualistic theory is that it provides a basis for further morphological and molecular genetic studies that might help to explain ovarian carcinogenesis.

Prevention of premalignancy of the ovary

Due to the lack of a clearly identifiable premalignant phase, prevention strategies have concentrated on either trying to identify early-stage lesions or removing the ovaries before disease develops, thereby aiming to impact on disease-associated morbidity and mortality. Various approaches have been tried in order to achieve this aim, including clinical, chemoprevention and prophylactic surgery.

The clinical approach has been predominantly aimed at screening with the serum tumour marker CA125, pelvic ultrasound or a combination of both modalities. Large clinical trials are currently underway, investigating the potential of such screening programmes in both low- and high-risk populations (i.e. UK Collaborative Trial of Ovarian Cancer Screening, UK Familial Ovarian Cancer Screening Study).

Chemoprevention has particularly focused on the use of the oral contraceptive pill, which has been shown to reduce the risk of ovarian cancer in both low- and high-risk populations (Hankinson et al 1992, McLaughlin et al 2007). The use of oral contraceptives in *BRCA* mutation carriers is currently not advised due to an apparent increase in the rate of breast cancer, although the data on this are limited.

Bilateral salpingo-oophorectomy has also been shown to reduce the risk of ovarian and fallopian tube cancer in *BRCA1* or *BRCA2* mutation carriers (Rebbeck et al 2009). The timing of surgery is dependent on the individual, their fertility requirements, the potential surgical morbidity and long-term hormonal sequelae. The current advice is that surgery should be considered once a woman reaches 35 years of age. Prophylactic surgery, however, does not completely remove the risk of malignancy since women in some high-risk populations are still at risk of developing primary peritoneal carcinoma (Finch et al 2006).

KEY POINTS

1. Infection with oncogenic high-risk HPV types is the central causal factor in the development of cervical neoplasia.
2. High-grade CIN has the potential to develop into invasive cancer in up to 30% of cases over a 20-year period.
3. 70% of cervical cancers might be prevented by HPV vaccination alone.
4. Cervical cytology can prevent 75% of cervical cancers by enabling early detection and treatment.
5. Colposcopy is subjective, has significant inter- and intraobserver error, and a sensitivity for high-grade disease of only 50%.
6. The diagnostic precision of cervical punch biopsies is not good. Invasive disease is not always detected and CIN2/3 may be substantially undercalled.
7. All excisional procedures used to treat CIN are associated with adverse obstetric morbidity, but only cold knife conization is associated with an increased rate of perinatal mortality.
8. The malignant potential of VAIN and VIN is uncertain.
9. Atypical endometrial hyperplasia should be managed as if cancer, as up to 45% of cases will be found to have endometrial cancer at hysterectomy.

Epidemiology

Cervical cancer is the most common gynaecological malignancy in the world with an estimated 493,000 new cases diagnosed each year (Ferlay et al 2004). It accounts for nearly 10% of all cancers in women. Although the incidence of cervical cancer has decreased in industrialized countries in the past 20 years, it still remains a major problem in the developing world. In most parts of Africa, South-Central Asia and Central America, cervical cancer accounts for 7–13% of all newly diagnosed cancers, with an incidence of 30–40 new cases per 100,000 population (Cancer Research UK, 2005).

In the UK, 2800 patients are diagnosed with cervical cancer per year, which accounts for approximately 2% of all female cancer cases, and 950 patients die from the disease (Cancer Research UK, 2005). With the introduction of the cervical screening programme in the UK, the incidence of cervical cancer has decreased from 16/100,000 in 1985 to 8/100,000 in 2005, while the incidence of carcinoma *in situ* has risen because of early detection with screening (Cancer Research UK, 2005). Carcinoma *in situ* is most common in women aged 35–39 years, while the incidence of cervical cancer is highest in women aged 30–34 years (17/100,000). The distribution of cervical cancer is bimodal, with a second peak reached in women aged over 85 years (14/100,000) (Cancer Research UK, 2005). Only 30% of cervical cancers are detected by screening, and the majority of cases occur in women who have never had a smear test or who have not been regular participants in the screening programme.

Aetiology

Epidemiological studies have long indicated a positive correlation between sexual activity and cervical cancer (Schiffman and Brinton 1995). Promiscuity, a sexual partner with promiscuous sexual behaviour and early age at first sexual intercourse have all been associated with a high risk of cervical cancer. It has been well demonstrated that human papilloma virus (HPV) infection is the major and probably a necessary causal factor, enhanced by several cofactors for both squamous cell carcinoma and adenocarcinoma of the cervix (Muñoz et al 1992, Schiffman et al 1993, Bosch et al 2002). HPV viral particles have been detected in almost all cases of cervical cancer (99.7%) (Walboomers and Meijer 1997, Franco et al 1999, Walboomers et al 1999).

Human papilloma virus

HPV is a double-stranded DNA virus that contains eight genes: six early (*E1*, *E2*, *E4*, *E5*, *E6*, *E7*) and two late (*L1*, *L2*). The early genes are expressed when the virus enters the host cell and encodes those proteins that regulate viral replication and the interaction with the host cell. The late genes code for capsid proteins.

E6 and *E7* encode oncoproteins. After the virus enters the host cell, *E6* and *E7* integrate into the host DNA and encode for oncoproteins. The *E6* oncoprotein binds to and destabilizes the host's *p53* tumour suppressor gene, resulting in a shorter half-life and inactivation. The *E7* oncoprotein binds to tumour suppressor genes *pRB*, *p21* and *p27*, resulting in increased cell proliferation.

Table 39.1 Risk groups of human papilloma virus (HPV)

High-risk HPV	16, 18, 31, 33, 35, 45, 51, 52, 58, 59, 68, 73, 82
Low-risk HPV	6, 11, 40, 42, 43, 44, 54, 61, 70, 72, 81

To date, more than 200 subtypes of HPV have been identified. According to oncogenic potential, HPVs can be classified as low-risk or high-risk types (Table 39.1) (Duenas-Gonzalez et al 2005, Smith et al 2007). Approximately 75% of cervical cancers are related to HPV 16 and 18 in Europe, and 90% of genital warts are caused by HPV 6 and 11 (Smith 2003). However, the distribution of HPV subtypes varies in other parts of the world (Smith et al 2007).

It is estimated that nearly 80% of sexually active women will acquire an HPV infection during their lifetime, while oncogenic subtypes are identified in 15% of the population (Brown et al 2005, Dunne et al 2007). Ninety percent of HPV infections will be eradicated by the host immune system, and only a minority of women will develop preinvasive disease or cancer (Pagliusi and Teresa Aguado 2004). The prevalence of HPV infection decreases with age, from approximately 20% in women aged 20–25 years to approximately 5% in women aged 50 years (Woodman et al 2001).

Cofactors

Cigarette smoking

Cigarette smoking has been linked with a higher risk of cervical cancer and has been demonstrated to be an independent risk factor (Winkelstein 1990, Kapeu et al 2009). High concentrations of nicotine metabolites have been detected in cervical mucus, and their molecular interaction with fragile histidine triad (*FHIT*) tumour suppressor gene has been investigated (Schiffman et al 1987, Holschneider et al 2005). The loss of function of *FHIT* plays an important role in early carcinogenesis (Pichiorri et al 2008). In comparison with non-smokers, smokers have impaired immune responses in the cervical epithelium and produce reduced levels of HPV 16/18 antibodies (Simen-Kapeu et al 2008).

A recent meta-analysis confirmed that smoking is an independent risk factor for squamous cell cervical cancer, but failed to demonstrate the same for adenocarcinoma (Berrington de González et al 2004).

Oral contraceptives

The association between long-term oral contraceptive (OC) use and cervical cancer is unclear. Recent analyses have shown an increased risk (relative risk 1.3–1.9) of cervical cancer amongst OC users (Smith 2003, Appleby et al 2007, Hannaford et al 2007). In contrast, others have reported that sexual behaviour differs between OC users and non-users, and that OC use is not an independent risk factor (Miller et al 2004, Syrjänen et al 2006).

Immunodeficiency

It has been observed that patients with immunodeficiency disorders, those on immunosuppressive therapy and those

with human immunodeficiency virus (HIV) infection are at higher risk of developing anogenital HPV-related premalignant changes and cancers. Cervical cancer is an acquired-immunodeficiency-syndrome-defining disease. One meta-analysis estimated a six-fold increased risk of developing cervical cancer for patients with HIV infection, and a two-fold increased risk for those with previous transplant surgery (Grulich et al 2007).

HPV vaccination

Cervical cytology

Cervical cytology is an effective secondary preventive measure. Since the identification of HPV as a causative factor for cervical cancer, laboratory research has focused on developing a primary preventive method, i.e. a vaccine against HPV.

HPV-virus-like particles have been developed that have similar antigenic properties to the virus itself, and therefore provoke a host immune response.

Two types of HPV vaccine have been developed: the bivalent Cervarix targeting HPV 16 and 18, and the quadrivalent Gardasil for HPV 6, 11, 16 and 18. The efficacy of Gardasil and Cervarix has been demonstrated in large, prospective, randomized trials (FUTURE II and PATRICIA) (FUTURE II Study Group 2007, Paavonen et al 2007). The vaccines are prophylactic and are not effective in patients with existing HPV infection. There is some cross-protection against other high-risk types of HPV.

Vaccination programme in the UK

The routine vaccination of 12–13-year-old girls with Cervarix has been introduced in the UK, and catch-up vaccination is available until 18 years of age. Three 0.5 ml injections are given at 0, 2 and 6 months. Immunity has been demonstrated for at least 5 years and long-term follow-up studies are ongoing.

Natural History and Spreading Pattern of Cervical Cancer

Cervical cancers can arise from the ectocervix or endocervix. Most ectocervical cancers are squamous in histology, and endocervical cancers arise from squamous and columnar epithelium. All cervical cancers are preceded by a preneoplastic stage (cervical intraepithelial neoplasia and cervical glandular intraepithelial neoplasia). Cervical cancers may present as an exophytic growth or an endophytic expansion without any visible tumour on the surface of the cervix.

The pattern of spread may be direct, lymphatic or haematogenous. The cancer can spread directly to the parametria, vagina, corpus, bladder and rectum. Primary sites of lymphatic spread are the external and internal iliac and obturator lymph nodes, while secondary sites are the presacral, common iliac and para-aortic lymph nodes. The most common sites of haematogenous metastases are lungs and liver.

Clinical Presentation

Patients with cervical cancer may be symptomatic or asymptomatic. Symptoms associated with cervical cancer are often non-specific, such as postcoital bleeding, intermenstrual bleeding, postmenopausal bleeding, excessive foul-smelling vaginal discharge and pelvic pain. Patients with locally advanced cancer can present with loin pain secondary to obstructive uropathy; sciatic pain due to compression of pelvic nerves; and fistula formation between the rectum, vagina and bladder. Renal failure is regarded as the most common cause of death by cervical cancer.

The positive predictive value of postcoital and intermenstrual bleeding for the diagnosis of cervical cancer in younger women is very low (Shapley et al 2006). Only 2% of patients with postcoital bleeding will be diagnosed with cervical cancer (Shapley et al 2006).

Asymptomatic patients are usually referred with either abnormal appearance of the cervix, a suspicious smear or an incidental discovery of cervical cancer on loop biopsy performed for treatment of intraepithelial neoplasia.

Diagnosis and Staging

Clinical examination

Apart from the routine medical history, special emphasis must be placed on the patient's desire for future fertility. Detailed examination is essential, including physical examination to exclude any obvious peripheral lymphadenopathy, speculum examination to assess the size of tumour and vaginal extension, and a rectovaginal examination to assess the size of cervical tumour and its extension to the parametria, vaginal vault and rectal mucosa. In cases of suspected bladder and bowel involvement, an examination under anaesthesia with cystoscopy and rectosigmoidoscopy is required, and biopsies are obtained for histological confirmation.

Pathology review

All patients referred with cervical cancer need to have their histology reviewed by a gynaecological oncopathologist. Information is obtained regarding the tumour histological type, differentiation, size (breadth \times horizontal width \times depth of invasion), pattern of invasion (uni- or multifocal, pushing or spreading), and presence or absence of lymphovascular space invasion.

Imaging in cervical cancer

Although cancer of the uterine cervix is staged clinically worldwide, a more precise assessment of the extent of cancer by cross-sectional imaging results in more tailored management. Magnetic resonance imaging (MRI) of the abdomen and pelvis is performed to assess the size and volume of tumour, the presence of parametrial invasion by analysing the integrity of the high-intensity stromal ring around the tumour, and to exclude bladder or rectum involvement. MRI is more accurate than computed tomography (CT) for assessment of local spread, and both modalities are superior to clinical examination.

Positron emission tomography (PET) is a functional scan that assesses the increased uptake of fluorodeoxyglucose (FDG). Organs with high metabolic activity (liver, brain, neoplastic tissue) have high FDG uptake. Addition of CT to PET (PET-CT) provides improved assessment of tumour localization. PET-CT has been used to assess para-aortic nodal status to facilitate planning of radiotherapy fields (Figure 39.1F) (Grigsby et al 2001). A further role of PET-CT is to assess the response to primary chemoradiotherapy, as well as early detection of cancer recurrences (Figure 39.2D).

Laparoscopic para-aortic lymph node sampling

Laparoscopic para-aortic lymph node sampling has been performed to assess the para-aortic lymph nodes; however, the only prospective randomized study failed to confirm therapeutic benefit (Lai et al 2003). The detection of micrometastasis in the para-aortic nodes has been used to modify radiation treatment fields (Leblanc et al 2007). Superiority of lymphadenectomy over PET-CT in assessment of the para-aortic nodes has not been established.

Multidisciplinary discussion

All patients must be discussed by a multidisciplinary team of gynaecological oncologists, clinical oncologists, medical oncologists, radiologists, pathologists and clinical nurse practitioners. Factors which influence management include:

- clinical staging;
- histological type;
- tumour size;
- volume of occult cancer;
- presence of adverse pathological risk factors;
- performance status and associated comorbidities;
- fertility status and plans; and
- patient's choice.

Staging

The International Federation of Obstetricians and Gynecologists (FIGO) staging of cervical cancer is based on clinical findings and, in the early stages, on the microscopic extent of the disease, and is not changed by intraoperative findings or the postoperative histological result (Table 39.2). When doubt exists regarding the stage of a particular cancer, the earlier stage should be chosen.

Surgical staging in cervical cancer is an issue that continues to generate discussion. Should lymph node status influence the staging? Should further substages be included? Should the histological findings and cross-sectional imaging influence the process of staging? A consensus statement from the International Gynecological Cancer Society meeting in 2006 reported as follows (Odicino et al 2007).

- Surgical staging is not practical, feasible or beneficial in the majority of cervical cancer patients, hence it is not recommended for staging. Nearly 80% of cervical cancer patients are diagnosed in the developing world, and the majority are diagnosed in late stages and are not suitable for surgical staging. Therefore, cervical cancer should remain a clinically staged disease.
- Pathological extent and other pathological findings such as lymphovascular space invasion (LVSI) should

Figure 39.1 Assessment of cervical cancer with magnetic resonance imaging. (A) Stage IB1 cervical cancer in the posterior lip of cervix (arrow). (B) Stage IB2 cervical cancer with bulky tumour replacing the cervix (arrow). (C) Stage IIB cervical cancer with right parametrial invasion. Note the interruption of the high-signal-intensity ring around the cervix on the right side (arrow). (D) Stage IIIB cervical cancer causing right hydronephrosis (arrow). (E) Stage IVA cervical cancer with fistula formation between the bladder and vagina (arrow). (F) Stage IVB cervical cancer with mediastinal lymphadenopathy (star). Note the increased uptake of left common iliac lymph nodes (arrow).

(C) Six months post treatment MRI scan. (D) Six months post treatment positron emission tomography-computed tomography scan with no uptake of fluorodeoxyglucose in the cervix. Note the increased uptake in the bladder.

be reported but not included in the staging of cervical cancer.

- Use of imaging techniques such as MRI, if available, is encouraged but not mandatory.
- Clinical investigations, including examination under anaesthesia, cystoscopy or sigmoidoscopy, which were previously mandatory for staging purposes are now optional and adopted for selected cases.
- The following modifications in cervical cancer staging would be adopted at the next FIGO meeting in 2009:
 - Stage 0 will be erased, as it is not an invasive disease.
 - Stage IIA: should be subgrouped similar to stage IB based on tumour size as stage IIA1 with tumour size less than 4 cm with involvement of up to two-thirds of the upper vagina, and stage IIA2 with tumour size greater than 4 cm with involvement of up to two-thirds of the upper vagina.
 - Stage IIB and IIIB: inclusion of unilateral or bilateral parametrial involvement. Stage IIB1 and IIIB1 indicate unilateral parametrial involvement, and stage IIB2 and IIIB2 indicate bilateral parametrial involvement.

Table 39.2 Revised FIGO staging of cervical cancer (2009)

Stage I	The carcinoma is strictly confined to the cervix (extension to the corpus would be disregarded)
IA	Invasive carcinoma which can be diagnosed only by microscopy, with deepest invasion ≤ 5.0 mm and largest extension ≤ 7.0 mm
IA1	Measured stromal invasion of ≤ 3.0 mm in depth and horizontal extension of ≤ 7.0 mm
IA2	Measured stromal invasion of >3.0 mm and not >5.0 mm with an extension of not >7.0 mm
IB	Clinically visible lesions limited to the cervix uteri or preclinical cancers greater than stage IA*
IB1	Clinically visible lesion ≤ 4.0 cm in greatest dimension
IB2	Clinically visible lesion >4.0 cm in greatest dimension
Stage II	Cervical carcinoma invades beyond the uterus, but not to the pelvic wall or to the lower third of the vagina
IIA	Without parametrial invasion
IIA1	Clinically visible lesion ≤ 4.0 cm in greatest dimension
IIA2	Clinically visible lesion >4.0 cm in greatest dimension
IIB	With obvious parametrial invasion
Stage III	The tumour extends to the pelvic wall and/or involves lower third of the vagina and/or causes hydronephrosis or non-functioning kidney [§]
IIIA	Tumour involves lower third of the vagina, with no extension to the pelvic wall
IIIB	Extension to the pelvic wall and/or hydronephrosis or non-functioning kidney
Stage IV	The carcinoma has extended beyond the true pelvis or has involved (biopsy proven) the mucosa of the bladder or rectum. A bullous oedema, as such, does not permit a case to be allotted to stage IV
IVA	Spread of the growth to adjacent organs
IVB	Spread to distant organs

* All macroscopically visible lesions, even with superficial invasion, are allotted to stage IB carcinomas. Invasion is limited to a measured stromal invasion with a maximal depth of 5.0 mm and a horizontal extension of not >7.0 mm. Depth of invasion should not be >5.0 mm taken from the base of the epithelium of the original tissue — superficial or glandular. The depth of invasion should always be reported in mm, even in those cases with 'early (minimal) stromal invasion' (~ 1.0 mm). The involvement of vascular/lymphatic spaces should not change the stage allotment.

[§] On rectal examination, there is no cancer-free space between the tumour and the pelvic wall. All cases with hydronephrosis or non-functioning kidney are included, unless they are known to be due to another cause.

Histology

The vast majority of cervical cancers (75%) are squamous cell carcinomas. The clinical appearance is usually exophytic, but it is not uncommon to have an endophytic tumour with a normal ectocervix. Histologically, three types of squamous cell carcinoma can be distinguished: large cell keratinizing, large cell non-keratinizing and small cell squamous carcinoma.

Adenocarcinoma is the second most common histological type and represents 20% of cervical cancers. The proportion

of adenocarcinomas compared with squamous cell carcinomas has increased significantly over the past three decades. The cause of this change is two-fold: relative, due to the gradual decrease in incidence of squamous cell carcinoma following the introduction of the cervical screening programme; and absolute, probably due to factors such as increased use of OCs (Ursin et al 1994, Smith et al 2000, Sasieni and Adams 2001). The gross appearance of adenocarcinomas is similar to squamous lesions; however, nearly 15% of patients present with clinically non-apparent lesions due to the endophytic expansion of the cancer (barrel-shaped cervix).

Microscopically, several subtypes are distinguished. The most common types are the endocervical (mucinous), intestinal and endometrioid variants.

It is a common clinical dilemma to distinguish between endocervical cancer with extension to the uterus and endometrial cancer of isthmic origin involving the cervical stroma. Clinical impression, cross-sectional imaging (MRI scan) and immunohistochemistry studies using p16 antibody can be of help to determine the origin of the cancer. The p16 protein is mainly expressed by HPV-related cancer cells.

Adenosquamous carcinomas consist of both squamous and glandular elements. A dedifferentiated form of adenosquamous carcinoma is the glassy cell carcinoma, which tends to occur in young patients and has a particularly aggressive clinical behaviour with poor outcome. Microscopically, it is characterized by large cells with glassy cytoplasm.

Neuroendocrine cervical carcinomas are rare histological subtypes, accounting for less than 5% of cervical cancers. They are characterized by highly aggressive clinical behaviour, manifesting as early nodal and distant diseases in more than half of patients. This results in poor survival despite multimodal treatment. Neuroendocrine cervical carcinomas are similar to the neuroendocrine cancers of the lung, both clinically and histologically. There are four subgroups: classical carcinoid, atypical carcinoid tumour, neuroendocrine large cell carcinoma and neuroendocrine small cell (oat cell) carcinoma (Albores-Saavedra et al 1997).

Clear cell carcinomas of the cervix are rare and have been linked with diethylstilboestrol exposure *in utero*. They usually present with large, exophytic tumours and are chemoradio-resistant. Surgery is therefore the cornerstone of management, followed by chemoradiotherapy.

Treatment of Cervical Cancer

Surgical management

The method of surgical treatment of cervical cancer depends on the stage of disease, tumour volume, histological features, patient's desire for future fertility and performance status. Treatment options for different stages of cervical cancer are shown in Table 39.3. The Wertheim-Meigs radical hysterectomy with pelvic lymphadenectomy has been the standard treatment for over a century in patients with stage IA2–IIA cervical cancer. Critical analysis of the data on the role of parametrectomy and pelvic lymphadenectomy has changed the practice significantly, and narrowed the indication for the radical operation. In stage IA2 and low-volume stage IB1 (<500 m³) cervical cancer, the risk of parametrial

Table 39.3 Management of cervical cancer

Stage	Treatment	LND
IA1	Cone biopsy/simple trachelectomy/simple hysterectomy	No
IA2	Cone biopsy/simple trachelectomy/simple hysterectomy	+/- (variable practice)
IA1/IA2 + LVSI	Cone biopsy/simple trachelectomy/simple hysterectomy	+
IB1: low volume (<500 mm ³)	Simple trachelectomy/simple hysterectomy	+
IB1: <2 cm diameter	Radical trachelectomy/radical hysterectomy	+
IB1: 2–4 cm diameter	Radical hysterectomy	+
IB2/IIA	Chemoradiation/radical hysterectomy	+
IIB–IVA	Chemoradiation/palliative surgery	
IVB	Chemotherapy +/- palliative radiotherapy	

LND, lymph node dissection.

involvement is low (<2%); therefore, simple hysterectomy is recommended (Stegeman et al 2007). Novel developments in surgical technique, such as fertility-sparing surgery (trachelectomy), laparoscopic radical hysterectomy, pelvic lymphadenectomy and para-aortic lymphadenectomy, have been developed and are practised increasingly. Sentinel node biopsy in cervical cancer is also being explored (Levenback et al 2002).

Stage IA1

The rate of metastasis to lymph nodes is less than 1%. Treatment options in the absence of lymphovascular space invasion are as follows.

- Conization for women who wish to preserve their fertility. Cold-knife cone biopsy is the preferred technique to prevent cauterized margins, which may affect histological assessment.
- Simple hysterectomy for women who do not wish to retain their fertility. This can be performed with ovarian conservation if desired.
- Simple trachelectomy for women with a short infravaginal cervix, where conization may be difficult to perform. Unlike radical vaginal trachelectomy (RVT), dissection of the ureter and removal of a vaginal cuff and parametrial tissue is not necessary. The technique is simple and involves a circular incision at the cervicovaginal junction, dissection of the vesicocervical space anteriorly and the pouch of Douglas posteriorly. The cervix is transected 1 cm below the level of the internal os. Insertion of a

cervical cerclage is necessary to retain the function of the cervical canal. This procedure is less morbid than a hysterectomy.

If therapeutic conization or trachelectomy is performed, the minimum desired surgical margin of clearance is 10 mm. Intraoperative frozen section analysis can exclude the presence of cancer at the surgical margin. If cervical intraepithelial neoplasia (CIN) extends to the resection margins, a repeat excision should be performed to remove the residual CIN and to exclude further invasive disease.

The presence of LVSI is generally considered to be a poor prognostic factor in cervical cancer (relative risk of recurrence 2.0) (Marchiole et al 2005). Therefore, for stage IA1 cervical cancer with extensive LVSI, pelvic lymphadenectomy might be considered in addition to simple hysterectomy or simple trachelectomy. However, this approach does not have a robust evidence base.

Stage IA2

The reported incidence of nodal involvement in stage IA2 cervical cancer varies from 0.5% to 10% due to the lack of uniformity in measurement of tumour dimensions (Hasumi et al 1980, van Nagell et al 1983, Simon et al 1986, Maiman et al 1988, Creasman et al 1998). The accepted surgical treatment for stage IA2 cervical cancer is pelvic lymphadenectomy with simple hysterectomy. However, in the presence of extensive LVSI, modified radical hysterectomy or RVT with pelvic node dissection has been recommended. It is debatable whether lymphadenectomy should be performed routinely in this substage as, by strict histological subgrouping of stage IA2 cervical cancer (i.e. depth of invasion 3–5 mm and horizontal dimension up to 7 mm), the true incidence of positive lymph node metastasis is 0.5% (1/205 histologically confirmed stage IA2) (Rogers and Luesley 2009).

Stage IB1 and IIA cervical cancer

Both surgery and chemoradiotherapy are thought to be equally effective for the management of stage IB1 and IIA cervical cancer. Surgical treatment which involves radical hysterectomy with pelvic lymphadenectomy has potential advantages in younger women by preserving ovarian function and avoiding radiotherapy-related late complications (e.g. vaginal stenosis, radiation cystitis and radiation-induced bowel damage). Complications related to radical surgery are usually temporary and short term (e.g. autonomic dysfunction of the bladder and rectum, shortening of the vagina, lymphoedema and lymphocysts). Careful preoperative selection of patients for radical surgery avoids subjecting them to double treatment (surgery followed by adjuvant treatment). If adverse histological factors are found in the surgical specimen, postoperative chemoradiotherapy is required (Table 39.4). Approximately 20% of patients with stage IB1 and IIA cervical cancer will require adjuvant chemoradiotherapy, which results in increased treatment-related morbidity.

The reported incidence of parametrial involvement in stage IB1 cervical cancer with tumour size less than 2 cm, depth of invasion less than 10 mm, negative pelvic lymph nodes and absent LVSI is low (0.4–0.6%) (Stegeman et al 2007, Wright et al 2007). This suggests that it may be advisable to avoid parametrectomy in this subgroup.

Table 39.4 Adverse histological prognostic factors in cervical cancer

Major risk factors	Minor risk factors
Positive pelvic nodes	Presence of lymphovascular space invasion
Parametrial invasion	Deep cervical stromal invasion (>1/3)
Positive or close (<5 mm) surgical margins	Large tumour size (≥4 cm)

Stage IB2 cervical cancer

The rate of pelvic lymph node metastasis in patients with bulky cervical cancer (>4 cm) is approximately 44% (Finan et al 1996). Although primary surgery is feasible and has some advantages (e.g. removal of tumour bulk, removal of bulky lymph nodes, proper assessment of tumour extension), due to the high likelihood of requiring double treatment, the logical option is primary chemoradiotherapy (NIH Consensus Development Conference Statement on Cervical Cancer 1997). The rate of pelvic relapse is significantly higher in patients with stage IB2 disease who had radiation alone compared with patients who had surgery followed by adjuvant radiotherapy (30% vs 20%) (Landoni et al 1997).

Neoadjuvant chemotherapy has been used with a rationale of reducing tumour bulk prior to surgery or radiotherapy, but no survival benefit has been demonstrated over conventional radiotherapy (Sananes et al 1998, Benedetti-Panici et al 2002).

Stage IIB–IVA cervical cancer

Surgical procedures (defunctioning colostomy, percutaneous nephrostomy) are performed in advanced cervical cancer, mainly for symptom control.

Surgical techniques

Radical hysterectomy

Radical hysterectomy was classified into five types by Piver et al in 1974 based upon the site of ligation of the uterine vessels and the radicality of parametrial resection. The Surgery Committee of the Gynecological Cancer Group of the European Organization for Research and Treatment of Cancer have produced, approved and adopted a revised version of the original Piver classification (Table 39.5) (Trimbos et al 2004). The salient steps of radical hysterectomy are (Figure 39.3):

- division of the round ligaments and dissecting the paravesical spaces;
- dissecting the utero-vesical space;
- isolating and dissecting the ureters and dissecting the pararectal spaces;
- ligating the uterine vessels at their origin;
- dissecting the ureteric tunnels and displacing the ureters laterally;
- dissecting the rectovaginal space;
- excising the cardinouterosacral complex;

Table 39.5 Modified Piver/European Organization for Research and Treatment of Cancer classification of radical hysterectomy

Class	Description
Type I	Simple hysterectomy.
Type II	Modified radical hysterectomy: the uterus, paracervical tissues and upper vagina (1–2 cm) are removed after dissection of the ureters to the point of their entry to the bladder. The uterine arteries are ligated at the site of crossing the ureters, and the medial half of the parametria and proximal uterosacral ligaments are resected.
Type III	Radical hysterectomy: en-bloc removal of the uterus with the upper third of the vagina along with the paravaginal and paracervical tissues. The uterine vessels are ligated at their origin, and the entire width of the parametria is resected bilaterally. Removal of as much of the uterosacral ligaments as possible.
Type IV	Extended radical hysterectomy: the difference from the type III procedure is that three-quarters of the vagina and paravaginal tissue are excised.
Type V	Partial exenteration: the terminal ureter or a segment of the bladder or rectum is removed, along with the uterus and parametria (suprlevator exenteration).

- excising the vaginal cuff; and
- completing the pelvic lymphadenectomy.

Landoni et al (2001) conducted a prospective randomized study comparing survival, relapse and morbidity between type II and type III radical hysterectomy for patients with stage IB and IIA cervical cancer. They found similar outcomes but a higher rate of late morbidity in the group with type III radical hysterectomy.

Okabayashi's nerve-sparing radical hysterectomy preserves both the hypogastric nerves and the splanchnic nerves in order to reduce bladder and bowel dysfunction (Fujii et al 2007). Laparoscopic radical hysterectomy is a novel approach with similar efficacy and recurrence rates to open radical hysterectomy, but with reduced blood loss and wound-related complications, and a shorter recovery period (Abu-Rustum et al 2003, Ghezzi et al 2007).

Removal of the tubes and ovaries is not routinely part of a radical hysterectomy. The risk of ovarian metastasis is 0.5% in early squamous cell carcinomas and 1.7% in adenocarcinomas (Sutton et al 1992). Therefore, for women under 45 years of age with cervical cancer, the ovaries can usually be preserved and can be transposed into the paracolic gutters out of the pelvis (outwith the potential radiation field). Conventionally, patients with adenocarcinoma are offered salpingo-oophorectomy; however, isolated ovarian metastasis in the absence of adverse pathological features is rare. The ovarian failure rate after transposition is 50% (Anderson et al 1993, Feeney et al 1995).

Type II–V radical hysterectomies are completed with systematic bilateral pelvic lymphadenectomy. The anatomical borders of the lymphadenectomy are the bifurcation of the common iliac vessels cranially, the deep circumflex iliac vein and the bladder caudally, the obturator internus muscle and the genitofemoral nerve laterally, the internal iliac artery medially, and the obturator nerve inferiorly (Figure 39.4).

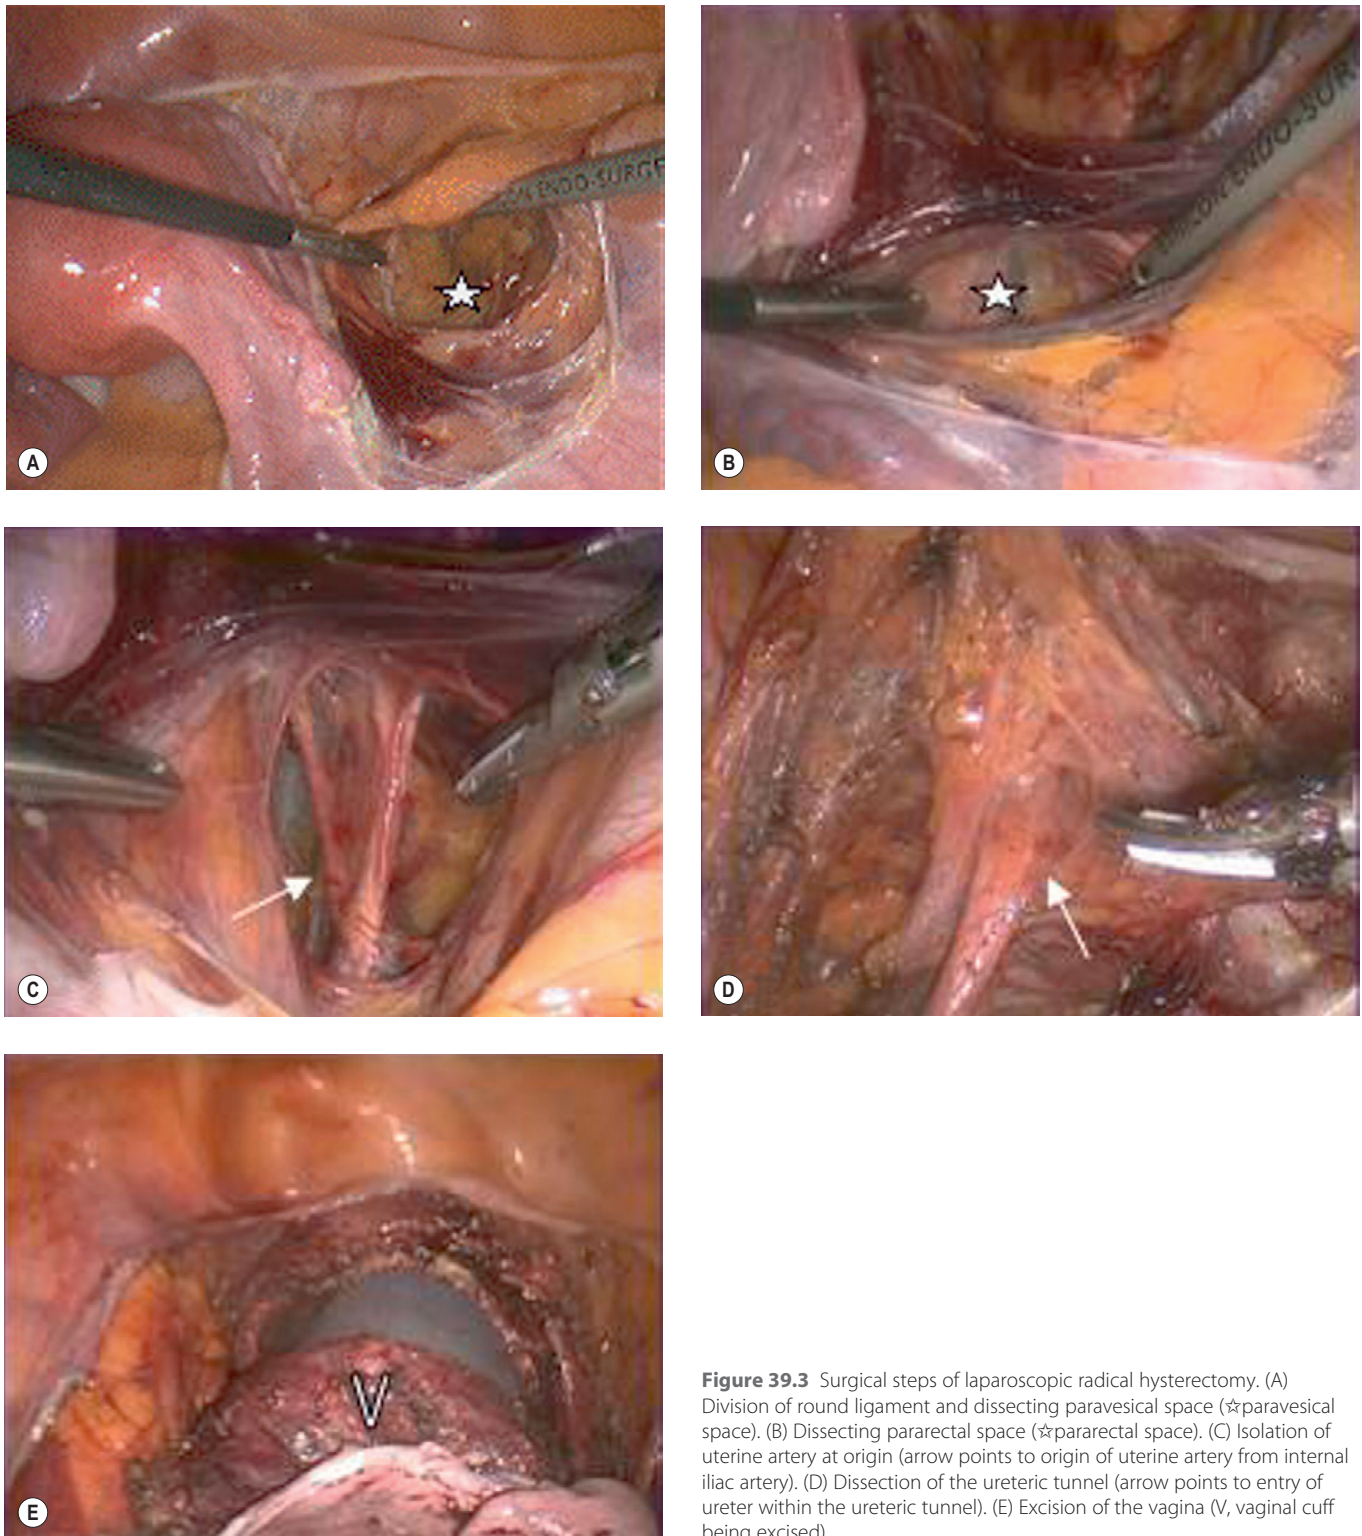

Figure 39.3 Surgical steps of laparoscopic radical hysterectomy. (A) Division of round ligament and dissecting paravesical space (☆paravesical space). (B) Dissecting pararectal space (☆pararectal space). (C) Isolation of uterine artery at origin (arrow points to origin of uterine artery from internal iliac artery). (D) Dissection of the ureteric tunnel (arrow points to entry of ureter within the ureteric tunnel). (E) Excision of the vagina (V, vaginal cuff being excised).

Any bulky para-aortic nodes should also be resected, given that radiation therapy cannot sterilize metastatic nodes larger than 2 cm in diameter (Hacker et al 1995).

Complications of radical hysterectomy

The complications of radical hysterectomy can be related directly or indirectly to the surgical procedure. Direct com-

plications can arise from injury to bladder, ureters, rectum, pelvic vessels and nerves, and these have to be managed intraoperatively. Indirect complications can result from devascularization of the ureters and can manifest as urogenital fistulae, usually 2–3 weeks postoperatively. Extensive parametrial dissection can damage the autonomic nerve supply of the bladder and rectum, resulting in voiding and

Figure 39.4 Anatomical landmarks of pelvic lymphadenectomy. EIA, external iliac artery; EV, external iliac vein; IIA, internal iliac artery; U, ureter; ON, obturator nerve; PM, psoas muscle.

evacuating difficulties. Removal of the upper part of the vagina may cause sexual dysfunction. Pelvic lymphadenectomy can result in formation of lymphocysts and development of leg lymphoedema. Damage to the obturator nerve during lymphadenectomy impairs the function of the adductor muscles.

Trachelectomy

In the UK, the peak incidence of cervical cancer is in women aged 35–39 years. As maternal age at first childbirth has increased progressively, it is not uncommon to find women with cervical cancer who have not yet started or completed their families (Cancerstats 2003). RVT is a fertility-preserving operation for the treatment of invasive cervical cancer, and was first reported by Dargent et al in 1994.

Selection criteria for trachelectomy

- Women wanting a further pregnancy.
- Size of cervical cancer less than 2 cm (up to 3 cm in selected cases with an exophytic tumour).
- Stage I1 and IA2 cervical cancer with LVSI.
- Stage IB1 cervical cancer.
- No evidence of pelvic lymph node metastasis.
- Presence of cervical cancer at least 1 cm away from internal cervical os on MRI.
- Non-neuroendocrine cervical cancers.

Procedure and technique

RVT is performed in two steps. Firstly, the pelvic lymph nodes are assessed laparoscopically to exclude metastasis. The second step is radical resection of the cervix along with a vaginal cuff and the paracervical tissue (Figure 39.5). Both procedures can be performed on the same day if a reliable frozen section facility is available. If not, laparoscopic lymphadenectomy can precede the radical trachelectomy by a few days. A circumferential incision is made on the upper vagina creating a 1–2 cm vaginal cuff. The vesicovaginal and paravesical spaces are dissected anteriorly and the pouch of Douglas is opened posteriorly. The knee of the ureter is

Figure 39.5 Trachelectomy specimen. PM, parametrium.

palpated in the bladder pillar, which is reflected upwards and medially. The bladder pillars are divided inferiorly, further releasing the bladder and ureters superiorly. The cardinal–uterosacral complex is clamped and divided just below the ureters. The cervix is then amputated leaving 0.5–1.0 cm of normal cervical tissue below the internal os. Cervical cerclage suture is inserted, the vagina is sutured in a circular fashion around the cervix and a new, vagino–isthmus junction is created.

Radical trachelectomy can also be performed abdominally and laparoscopically (Cibula et al 2005). The abdominal approach is suitable in women with poor vaginal access, when the cervix is flush with the vault or in the presence of a large, exophytic cervical growth (Cibula et al 2008). Pelvic lymphadenectomy is usually performed laparoscopically, but can also be performed by an extraperitoneal approach.

Outcome after radical vaginal trachelectomy

Potential morbidities after RVT are bladder and ureteral injury, bladder dysfunction, haematoma, lymphoedema and cervical stenosis with haematometra (Plante et al 2005). The reported recurrence rate after RVT is 4% (Milliken and Shepherd 2008). Common sites of recurrence are the vagina, parametrium, pelvic sidewall and para-aortic lymph nodes. Central recurrences may be attributable to either persistent disease in the isthmus or persistent high-risk HPV infection (Morice et al 2004). In the presence of poor histological prognostic factors, additional treatment may be recommended, including completion radical hysterectomy if the margins of clearance are less than 1 cm, or chemoradiation if more than one poor prognostic factor is present (Table 39.4).

Obstetric outcome after radical trachelectomy

Out of 780 RVT procedures reported to date, there have been 302 pregnancies with 190 live births (Shepherd and Milliken 2008). Following RVT, a significant proportion (57%) of patients did not attempt any further pregnancy. In those who did, there was a 70% conception rate with a 30% pregnancy loss during the first and second trimesters, and a preterm

delivery rate of 20%. Pregnancies after RVT should be accorded high-risk status because of the increased risk of miscarriage, ascending infection, premature membrane rupture and preterm labour. Regular screening for bacterial vaginosis, prophylactic antibiotics, antenatal steroid therapy and elective caesarean section are recommended.

Follow-up after radical vaginal trachelectomy

Follow-up practices are varied in terms of intervals, duration and modalities used. Shepherd and Milliken (2008) recommend 4-monthly visits for 3 years, and 6-monthly visits until 5 years. Endocervical and vaginal vault cytology and colposcopy are performed during follow-up. HPV testing may be recommended in the presence of persistent dyskariotic cytology on follow-up smears (Singh et al 2004).

Sentinel lymph node biopsy in cervical cancer

The sentinel node is defined as the first lymph node or group of nodes that drains the anatomical site of the tumour. The status of the sentinel node should represent the whole lymphatic area, meaning that if the sentinel node is negative, the non-sentinel lymph nodes should also be negative. The application of sentinel node dissection in breast and vulval cancer has resulted in a decrease in treatment-related morbidity.

Sentinel lymph node biopsy in cervical cancer has not become a routine practice outside clinical trials. Potential advantages of sentinel node biopsy in cervical cancer are to facilitate treatment planning; for example, if the sentinel node is positive, the radical surgery can be abandoned in favour of chemoradiotherapy. Similarly, if the sentinel node is negative, extensive lymphadenectomy can be avoided and the surgical morbidity of complete pelvic lymphadenectomy can be minimized. Sentinel lymph node biopsy is feasible in cervical cancer as the tumour is visible and it is easy to inject radionuclide colloid (99m technetium) and blue dye. All potential sites of lymphatic drainage of the uterine cervix are accessible through the laparoscope.

Limitations of sentinel node dissection in cervical cancer are:

- multiple sentinel nodes may be identified and there is a risk of skip metastases to para-aortic, common iliac and presacral lymph nodes in 4%, 5% and 8% of cases, respectively; and
- a sentinel node may be identified in more than one site.

Technique of sentinel node biopsy in cervical cancer

Radionuclide tracer 99m technetium sulphur colloid (1 ml) is injected around the cervical tumour in four quadrants, followed by lymphoscintigraphy performed a few hours prior to surgery. Immediately prior to surgery, 2 ml of blue dye diluted with 2 ml of normal saline is injected in four quadrants around the cervical tumour. Laparoscopic identification and retrieval of the sentinel node using a gamma probe is performed (Figure 39.6). Using a combination of radioactive colloid and blue dye increases the identification of sentinel nodes to 98%. Histological ultrastaging and immunostaining with pancytokeratin further increase the detection of micrometastases.

Radiotherapy

Radiation therapy can be used as primary treatment for all stages of cervical cancer, and as an adjuvant treatment after surgery in the presence of adverse histological features. In cases of disseminated cancer, it can be administered with palliative intent to achieve symptom control in the pelvis. Radiotherapy can be used as curative or palliative therapy for recurrent cervical cancer.

Recently, three randomized trials administering concurrent chemotherapy (cisplatin) and radiotherapy to patients with locally advanced cervical cancer demonstrated a significant benefit in progression-free and overall survival compared with radiotherapy alone (Keys et al 1999, Morris et al 1999, Rose et al 1999, Bekkers et al 2002). Since these seminal trials, chemoradiation therapy has become the standard treatment for medically fit patients with locally advanced cervical cancer. Concurrent chemotherapy enhances the effect of radiotherapy in two ways: certain chemotherapeutics (e.g. cisplatin, hydroxyurea) behave as radiation sensitizers, and the chemotherapy itself is cytotoxic.

Primary radiotherapy

Although all stages of cervical cancer can be treated with radiotherapy, surgical management is preferred in the early stages (stage IA1, IA2 and IB1) to avoid complications of radiotherapy. Primary radiation therapy with chemotherapy, however, is the cornerstone of management for stage IB2, IIA–B, IIIA–B and IVA cervical cancers. There are two main types of radiotherapy: external beam radiation and vaginal brachytherapy. They are usually used in combination.

External beam radiotherapy (teletherapy)

The objectives are to control the primary tumour as well as the parametria and the pelvic sidewalls containing lymphatic tissue. The borders of the radiation field are:

- inferior: the mid-pubic line;
- superior: the superior aspect of the L5 vertebra; and
- lateral: 1 cm lateral to the bony pelvis.

In cases of positive para-aortic lymph nodes, the field can be extended up to the level of the renal vessels. The maximum dose of radiation to the tumour can be delivered using two opposed fields (anterior and posterior) or the four-field technique (anterior, posterior, left and right lateral). The latter usually produces a more favourable dose distribution, delivering less radiation to the bladder and rectum.

Radiation dose

The treatment consists of 25 fractions of external beam radiation therapy (50 Gy) with weekly cisplatin (40 mg/m²), which reduces the central tumour mass and facilitates subsequent brachytherapy to optimally control the rest of the disease.

Brachytherapy

Placement of radioactive material into a body cavity is called 'brachytherapy'. Various delivery techniques are used. The Manchester applicator consists of a uterine probe and a pair of intravaginal receptacles (Figure 39.7). The patient is

Figure 39.6 Sentinel lymph node biopsy in cervical cancer. (A) Whole-body scintigraphy. (B) Identification of sentinel node by blue dye technique. (C) Identification of sentinel node using gamma probe. (D) Laparoscopic retrieval of sentinel node.

isolated in a shielded room and remote control is used to deliver the radioactive particles into the applicators. There are two main forms of brachytherapy:

- low-dose-rate brachytherapy, which delivers a single dose of 25–27 Gy over 10–15 h; and
- high-dose-rate brachytherapy, with shorter (20 min) but multiple (two to three) applications of a total dose of 15–20 Gy.

Brachytherapy delivers a high dose of radiation to a small volume of target tissue surrounding the applicator. The radiation dose falls off rapidly over a short distance, minimizing the radiation effects to normal surrounding tissues. Retraction of the rectum and bladder with vaginal packing can further reduce radiation-related complications.

Vaginal brachytherapy is critically important to control the central tumour mass adequately. The omission of brachytherapy will result in a higher locoregional relapse rate (Lanciano et al 1991, Logsdon and Eifel 1999).

Figure 39.7 Manchester applicator.

Two primary reference points are identified to deliver the optimal dose of radiation to the cervical tumour:

- point A: 2 cm lateral and 2 cm superior to the external cervical os; and
- point B: 3 cm lateral to point A.

Adjuvant radiotherapy

Adjuvant radiation therapy is administered in combination with chemotherapy. Adjuvant therapy in the presence of one major risk factor or at least two of the three minor adverse factors (Table 39.4) reduces the risk of recurrence, and increases recurrence-free survival (Sedlis et al 1999).

Emergency and palliative radiotherapy

Patients with advanced cervical cancer presenting with profuse haemorrhage can be managed effectively with a total dose of 5–30 Gy external beam pelvic radiation in multiple fractions. Patients with unresectable para-aortic lymph node mass, symptomatic supraclavicular or mediastinal lymph node enlargement, or bony metastasis may also benefit from palliative radiotherapy and chemotherapy.

Complications of radiation therapy

Complications of radiotherapy depend on radiation-related factors and patient-related characteristics. The total dose of radiation, the dose per fraction and the total volume irradiated are proportionately related to radiation-related complications. Factors related to the patient, such as previous pelvic inflammatory disease, history of smoking, diabetes, hypertension or previous pelvic surgery, will increase the risk of complications. Acute complications (e.g. skin reactions, diarrhoea and anaemia) are usually mild.

Late complications can occur many months or years after treatment and are usually chronic.

- Bladder complications: radiation cystitis manifesting as haematuria, frequency and dysuria.
- Bowel complications: radiation enteritis presents with severe diarrhoea, malabsorption, cachexia or bowel obstruction.
- Fibrosis of the pelvic structures resulting in reduced bladder capacity and pelvic pain.
- Fusion of the vaginal walls and shortening of the vaginal resulting in dyspareunia and altered sexual function.
- Fistulae: rectovaginal or vesicovaginal fistula formation is a major complication with a significant adverse impact on quality of life.

Recurrent Cervical Cancer

The risk of recurrence depends on the extent of the primary cancer at presentation. Approximately 10–20% of patients with stage IB–IIA cervical cancer with negative lymph nodes will recur, compared with up to 70% of patients with nodal metastasis or locally advanced disease (Table 39.6).

Recurrences can be locoregional or distant (Table 39.7). Patients with pelvic recurrence usually present with vaginal bleeding, discharge, pelvic pain and sciatic pain. Patients

with disseminated recurrence will develop systemic symptoms associated with cachexia.

When such symptoms are present, the following investigations should be considered:

- clinical examination (rectovaginal and speculum examination, assessment of peripheral lymph nodes);
- cross-sectional imaging (MRI of pelvis and abdomen, CT of chest);
- examination under anaesthesia, biopsies, cystoscopy and rectosigmoidoscopy; and
- PET–CT scan in cases of central pelvic recurrence to exclude extrapelvic disease.

Treatment of recurrent cervical cancer depends upon the site and extent of recurrence, type(s) of previous treatment, time elapsed since primary treatment and the patient's performance status. The aim of treatment may be curative or palliative depending upon the distribution of disease.

Pelvic recurrence after surgery

Patients not initially treated with radiation therapy can be considered for external beam radiotherapy for their recurrence.

Pelvic recurrence after radiotherapy

Patients with local pelvic relapse who have previously been treated with primary or adjuvant radiotherapy may be considered for curative surgical treatment provided that the

Table 39.6 Rate of pelvic and distant recurrences in cervical cancer

Stage	Pelvic recurrence (%)	Distant metastasis (%)
IB	10–14	16
IIA	17–20	31
IIB	23	26
III	42	39
IVA	74	75

lesion is confined to the pelvis and does not extend to the pelvic sidewall. All patients should undergo PET-CT to exclude extrapelvic disease. The classic triad of leg oedema (suggestive of nodal infiltration), leg pain (suggestive of nerve infiltration) and hydronephrosis (suggestive of pelvic side wall infiltration) are contraindications to therapeutic exenteration. Depending on the site and extent of recurrence, pelvic exenteration, originally described by Brunschwig, can be either total, anterior or posterior. Total exenteration involves removal of the anterior (bladder and urethra), middle (vulva, vagina and perineum) and posterior (anal canal, rectum and sigmoid) compartments; anterior exenteration involves removal of the anterior and middle compartments; and posterior exenteration involves removal of the middle and posterior compartments. Depending upon the cranio-caudal extent of tumour involvement, the exenteration is termed 'suprlevator' when the levator ani muscle is preserved, and 'translevator' when both the supra- and infralevator compartments are resected.

Exenterations are significantly morbid surgical procedures with a major degree of psychosexual impact. Patients require extensive preoperative counselling and postoperative support. With careful selection, the 5-year survival rate after anterior and posterior exenteration is 30–60% and 20–40%, respectively (Friedlander and Grogan 2002).

Patients with sidewall recurrences of less than 5 cm in diameter can be considered for laterally extended endopelvic resection, and can achieve a 5-year survival rate of up to 60% (Hockel 2003).

Disseminated recurrence

For multiple site or distant recurrence, chemotherapy can be administered with a palliative intent. Cisplatin is usually administered in doses of 50–100 mg/m² every 3 weeks, either alone or in combination with paclitaxel or gemcitabine.

Follow-up after Treatment of Cervical Cancer

Follow-up is aimed to detect recurrent disease, assess treatment-related morbidity, and analyse psychosocial and psychosexual morbidity. There is no standardized effective protocol for follow-up in cervical cancer. Vault cytology is not effective in detecting recurrences of cervical cancer and is not recommended (Bodurka-Bervers et al 2000). Symptom status at the time of recurrence is a significant predictor of survival; the median survival is 11 months for symptomatic recurrence and 42 months for asymptomatic recurrence. Routine clinical examination in asymptomatic patients appears to lack sensitivity, as a high proportion of recurrences are not detected until symptoms are apparent.

In an observational study of 993 cases of stage IB cervical cancer treated with surgery or radiotherapy, 63% of recurrences occurred before 24 months and 77% occurred before 36 months. The median time to relapse was 16 months (Bodurka-Bervers et al 2000). Patients should be followed-up every 4 months for at least 2 years. MRI and CT are performed whenever recurrence is suspected, but have limitations in differentiating postradiotherapy fibrosis from recurrent tumour. PET-CT scan has been demonstrated as a more sensitive modality for post-therapy

surveillance for the detection of recurrent and persistent cervical cancer in both symptomatic and asymptomatic patients. There is limited evidence regarding the optimal timing and frequency of post-therapy scans (Figure 39.2). PET-CT scans should not be used within 3 months of the primary treatment to reduce false-positive results, as the therapeutic effect of radiation continues even after completion of treatment. PET-CT scan is able to identify persistent disease in patients following completion of chemoradiotherapy to select patients for salvage hysterectomy or exenteration.

The tumour marker squamous cell carcinoma antigen is neither sensitive nor cost-effective in the follow-up of cervical cancer and is not recommended (Chan et al 2002).

Management of Complications in Advanced Disease

Patients with advanced cervical cancer may develop the following distressing symptoms.

- **Pain:** due to direct nerve infiltration or nodal enlargement impinging on pelvic nerves. This can be managed with oral analgesics such as acetaminophen, non-steroidal anti-inflammatory drugs (NSAIDs), opiates given as oral or intramuscular morphine, fentanyl patches, nerve blocks and gabapentin for neuropathic pain.
- **Renal failure:** due to bilateral ureteric obstruction caused by bilateral parametrial infiltration extending to the pelvic sidewalls, or extrinsic compression from an enlarged nodal mass. Prerenal and renal causes of failure should always be excluded. The management of obstructive uropathy is dependent upon the general condition of the patient, quality of life, and the wishes of the patient and her relatives. Management of ureteric obstruction is controversial as the medical intervention to relieve ureteric obstruction may convert a peaceful death from uraemia to a more painful and distressing terminal phase. If further useful palliative intervention is available, the treatment options include either percutaneous nephrostomy, retrograde stenting or urinary diversions.
- **Thrombosis:** patients with advanced cervical cancer are at high risk of thrombosis. Thrombosis can result from the compression of pelvic vessels by tumour masses, impaired mobility, the effects of treatment or cancer-related vascular factors. Treatment with low-molecular-weight heparin is recommended if thrombosis is confirmed.
- **Haemorrhage:** this can result from erosion of blood vessels on the surface of an exophytic or ulcerating growth. Invasion of the bladder or bowel can result in haematuria or rectal bleeding. Treatment is dependent upon the extent of bleeding. Minor bleeding is improved with oral tranexamic acid, withholding any NSAID therapy, vaginal packing or a single fraction of radiotherapy. Heavier arterial bleeding is usually fatal.

It is essential to forewarn the relatives or carers of the patient with advanced cervical cancer so that they will be prepared for any of the above events. If the patient is

in a preterminal stage, treatment is aimed at keeping the patient comfortable with sedation and anxiolytics such as midazolam.

- Malodorous discharge: results from tumour necrosis or fistulae. Oral or topical metronidazole reduces the odour.
- Fistulae: cervical cancer can erode into both the bladder and the bowel. If the patient is not suitable for any exenterative procedure, urinary diversion surgery such as an ileal conduit can be performed when both ureters are implanted into a segment of ileum and drained via a stoma. Ileostomy or colostomy can be performed to relieve symptoms from bowel fistulae.

Cervical Cancer in Pregnancy

Pregnancy has no adverse effects on the natural history or the prognosis of cervical cancer. If cervical cancer is detected prior to 16 weeks of gestation, immediate treatment is recommended irrespective of its stage. If cervical cancer is detected after 16 weeks of gestation and is at an early stage (IA1–IB1), treatment can be delayed until fetal maturity. Antenatal steroid administration will promote fetal lung maturity. Elective caesarean section with simple hysterectomy is performed for stage IA2 cervical cancer, and Wertheim's radical hysterectomy is performed for stage IB1 cervical cancer. Patients with stage IA1 cervical cancer require laser loop excision of the transformation zone or cold-knife

conization 6 weeks postnatally. For pregnant patients with advanced cervical cancer (stage IB2 or greater) diagnosed after 16 weeks of gestation, consideration for delay up to 4 weeks must be based on the gestational age at the time of diagnosis. Classical caesarean section is the recommended mode of delivery if the fetus has reached the stage of viability, in order to avoid damage to the cervix.

Conclusions

The management of cervical cancer continues to develop and become more individualized to meet each patient's needs. This has occurred against a background of decreasing incidence in the developed world. Efforts have been focused to reduce treatment-related morbidity and prolong survival with improved quality of life. Recent developments in the management of cervical cancer include wider use of laparoscopic techniques (laparoscopic Wertheim's radical hysterectomy, and pelvic and para-aortic lymphadenectomy), use of the sentinel node technique, use of PET–CT scan for pretreatment assessment and post-treatment follow-up, neoadjuvant chemotherapy prior to chemoradiation and radical primary surgery. The techniques of extensive pelvic sidewall resection for primary (total mesometrial resection) or recurrent cancer (laterally extended endopelvic resection) have been developed recently to enhance patient survival with acceptable morbidity.

The more difficult challenge will be to impact on cervical cancer cases occurring outwith the developed world.

KEY POINTS

1. In England and Wales, the incidence and mortality of cervical cancer have been decreasing as a result of the introduction of organized screening. Cervical cancer remains the second most common cancer in women worldwide.
2. The cause remains unknown, but HPV infection is widely believed to be a key step. HPV infection is very common in young people, implying that some other factors are necessary before cancer will develop.
3. Conservative treatment of microinvasive lesions should only be considered where invasion is less than 3 mm from the nearest basement membrane and lymphatic channel involvement is not seen.
4. Squamous cell carcinoma is the most common type of cervical cancer and has a similar prognosis to adenocarcinoma. Undifferentiated tumours have a poor prognosis.
5. Metastatic spread is mainly lymphatic, and involvement of the parametria is initially focal rather than confluent.
6. The volume of the primary tumour is one of the most important indications of prognosis after the status of the lymph nodes.
7. MRI with an endovaginal coil gives the best estimate of the volume of the tumour, but MRI is not reliable in identifying nodal disease.
8. Overall, 42% of women with cervical cancer die within 5 years.
9. Surgery is most often performed on the younger patient with lower-volume stage IB disease.
10. Radiotherapy is used for older and less fit patients, regardless of the size of the tumour, and for women with bulky stage IB and IIA tumours or with more advanced disease.
11. Chemoradiation offers a small increase in cure rate but at the cost of increased immediate toxicity.

Patients with vulval symptoms are not uncommon in gynaecological practice. The complaint is often longstanding, distressing and frequently induces a feeling of despair in both patient and doctor. A careful, sympathetic approach and a readiness to consult colleagues in other disciplines are essential. Even when it seems that no specific therapy can be offered, many patients are helped by the knowledge that there is no serious underlying pathology and by a supportive attitude.

Development and Anatomy

The vulva and vagina develop in association with the urogenital sinus, the caudal end of the paramesonephric or Müllerian ducts, and the development of the anus posteriorly and bladder and urethra anteriorly. Debate continues regarding how much of the lower vagina, hymen and vestibule originate from the ectoderm, the endoderm of the hindgut forming the urogenital sinus and the mesoderm of the paramesonephric ducts. Developmental abnormalities are not unusual and range from a single cloaca to variations in vaginal development, including agenesis or the presence of a transverse or midline septum.

The vulva consists of the labia majora, labia minora, mons pubis, clitoris, perineum and the vestibule. The labia join anteriorly at the anterior commissure and merge posteriorly into the perineum, the anterior margin of which is the posterior commissure. From puberty, the mons and lateral parts of the labia majora are covered in strong

coarse hair and are distended with subcutaneous fat. In addition to hair follicles, they contain sebaceous and sweat (eccrine and apocrine) glands. The labia minora are two smaller, longitudinal, cutaneous, non-hair-bearing folds medial to the labia majora and extending from the clitoris for a variable distance beside the vestibule to end before reaching the perineum. The labia majora and minora are separated from each other by the interlabial fold, and may contain prominent or tortuous veins during pregnancy and later life. The labia minora contain numerous blood vessels, nerve endings and sebaceous glands. There is considerable variation in size and shape from woman to woman, and gross enlargement or asymmetry can occur. Anteriorly, they fuse above the clitoris to form the prepuce and below the clitoris to form the frenulum. The labia minora have an important role during sexual arousal when they become engorged and extend or are pushed outwards to allow coital entry; when flaccid, they serve to protect the vestibule and access to the urethra and vagina (O'Connell et al 2008).

The clitoris consists of a body formed of the two corpora cavernosa composed of erectile tissue enclosed in a fibrous membrane and attached to the puboischial ramus on each side by the crus. The body of the clitoris ends in the glans which also contains spongy tissue and nerve endings. The clitoris has a rich blood supply which comes from the terminal branches of the pudendal arteries.

The vagina consists of a non-keratinized squamous epithelial lining supported by connective tissue and surrounded by circular and longitudinal muscle coats. Vaginal epithelium

has a longitudinal column on the anterior and posterior walls, and from each column, numerous transverse ridges or rugae extend laterally on each side. The squamous epithelium is thick and rich in glycogen during the reproductive years. It does not change significantly during the menstrual cycle. The prepubertal and postmenopausal vaginal epithelium is thin or atrophic. Engorgement and transudation of the distal vagina are important components of normal sexual response.

The vulvovaginal vestibule is the cleft between the labia minora. It is covered by non-keratinized squamous epithelium and extends cranially from the hymen to reach the keratinized skin at Hart's line. The vestibule contains the entrance to the vagina, the urethral meatus, and the ducts of the greater (Bartholin's) and lesser vestibular and periurethral glands. Further features are included below in the section on vulvodynia.

Classification of Vulval Disease

Terminology of lesions and conditions of the vulva has caused confusion because of the many and complex names used, sometimes for similar changes. The International Society for the Study of Vulvovaginal Disease (ISSVD) has published a classification of vulvar dermatoses (Lynch et al 2007) (Box 40.1). Its use is not universal but it serves as a starting point to group some of the diseases described in this chapter.

Presentation of Vulval Disease

The majority of women present with vulval pruritus (itch) and associated scratching. Others will present with pain, burning, soreness, rawness, stinging or irritation but without scratching. However, the symptoms do not necessarily imply a particular condition. Sometimes a lesion will be noted as white, red or pigmented, or as raised or ulcerated. Some lesions will be asymptomatic.

The onset of symptoms will sometimes be associated with other life events such as following a course of antibiotics, a diagnosis of certain medical disorders, the introduction of certain therapeutic drugs or withdrawal of systemic corticosteroids. A full medical history will sometimes identify other conditions with vulval manifestations, and dental details should not be overlooked. Some patients with vulvovaginal lichen planus will already have a diagnosis of oral lichen planus; Belfiore et al (2006) found that 57% of women with oral lichen planus also had vulval lichen planus. Many patients will present with a list or bag full of topical treatments that they have used previously. A comprehensive list is useful because those drugs that have helped or caused deterioration can be identified, and this will also allow confident prescription of a preparation not yet tried.

Examination of the Patient

General examination of the patient should include inspection of the buccal, lingual and gingival mucosa and the skin of the face, hands, finger nails, wrists, elbows, scalp, trunk

and knees. Evidence of systemic disease such as diabetes, and hepatic, renal or haematological disease should be sought. Where appropriate, urinalysis or blood testing should also be performed.

A combined clinic conducted by gynaecologists, dermatologists and genitourinary physicians has considerable merit (McCullough et al 1987). Facilities should include adequate lighting, a tilting examination chair to obtain access to the posterior part of the pudendum, a colposcope, and a camera for colpophotography and clinical photography.

Examination should consist of inspection of the vulva including the vestibule, urethral meatus, perineum and perianal area. Patients with neoplastic disorders must also have the cervix and vagina examined, but many older patients and those with lichen sclerosus will not tolerate a speculum examination and, unless there is any specific symptom, it is unnecessary to include this as part of the examination.

Colposcopic assessment of the vulva is not essential if there is an obvious, readily diagnosed lesion and there are

Box 40.1 ISSVD 2006 classification of vulvar dermatoses: pathological subsets and their clinical correlates

Spongiotic pattern

Atopic dermatitis
Allergic contact dermatitis
Irritant contact dermatitis

Acanthotic pattern (formerly squamous cell hyperplasia)

Psoriasis
Lichen simplex chronicus
Primary (idiopathic)
Secondary (superimposed on lichen sclerosus, lichen planus or other vulvar disease)

Lichenoid pattern

Lichen sclerosus
Lichen planus

Dermal homogenization/sclerosis pattern

Lichen sclerosus

Papular genitocrural acantholysis

Granulomatous pattern

Crohn's disease
Melkersson–Rosenthal syndrome

Vasculopathic pattern

Aphthous ulcers
Behçet's disease
Plasma cell vulvitis

no suggestions of neoplastic change. However, colposcopy is valuable if the patient is symptomatic but no lesion can be seen, if there is difficulty in interpreting or defining the limits of the visible lesions, and to select an appropriate site for biopsy. The techniques are described elsewhere (MacLean and Reid 1995). The vascular patterns can be complex and may be associated with neoplasia. Sometimes, sites of previous biopsies will develop unusual vascular patterns associated with healing. Excessive applications of potent topical corticosteroids will exaggerate vascularity with prominent telangiectasia and thinned epidermis.

Once the vulva has been scanned with the colposcope, aqueous acetic acid solution should be applied. It is important to realize that the aceto-white changes will not be as dramatic as those seen on the cervix, and may not be apparent in areas of abnormal keratinization. Aceto-white epithelium may represent vulvar intraepithelial neoplasia (VIN) or viral changes with human papilloma virus (HPV) and Epstein-Barr virus, as well as tissue repair with ulcers and erosions, scratch damage or coital trauma. It is incorrect to interpret the papillae seen in the vestibule as 'microwarts'; Jonsson et al (1997) showed that aceto-white changes in the vulva were a poor predictor of viral presence.

In the past, histological diagnosis of the vulval lesions depended on inpatient biopsy performed under general anaesthesia. Very appropriate biopsy material can be obtained using a 4 mm diameter Stiefel disposable sterile biopsy punch, and this can be performed as an outpatient procedure under local anaesthesia (McCullough et al 1987). A silver nitrate stick with a small plug of cotton wool or, alternatively, ferric subsulphate (Monsel's solution) is applied for haemostasis.

Prevalence of Vulval Lesions

Box 40.2 shows the range of lesions seen in a combined vulva clinic (MacLean et al 1998). There may be some bias

Box 40.2 Prevalence of vulval lesions seen in 1000 women

in these figures because the clinic received referrals from gynaecologists, and because the authors' research interests included vulval precancer and pain.

Infections included recurrent candidiasis, bacterial vaginosis, trichomoniasis, herpes simplex virus, condyromata acuminata, ulcers associated with human immunodeficiency virus, hidradenitis suppurativa, *Enterobius vermicularis* (threadworms) and vulva lymphoedema secondary to filariasis, and were not enumerated because they sometimes coexisted with other conditions.

Use of Topical Corticosteroids

As many gynaecologists are apprehensive about the use of topical corticosteroids in the vulval area, some basic information is desirable.

Topical steroids are effective in the management of inflammatory changes but are contraindicated in the presence of untreated infection. In some situations, corticosteroids can be combined with an antifungal or antibacterial agent, but care must be taken with the latter because an allergic contact dermatitis can develop.

Topical preparations are suspended in a vehicle, usually as a cream or ointment. Creams are miscible with skin secretions, easy to apply smoothly (and sparingly) but may contain additive to which the patient will become sensitized. Ointments are usually insoluble in water, greasy in texture and therefore more difficult to apply and more occlusive than creams. As they encourage hydration, they are better suited for dry lesions. Pastes are stiffer but useful for localized lesions. They are less occlusive than ointments and can be used to protect excoriated or ulcerated lesions.

Topical corticosteroids are graded according to their potency, which reflects the degree of absorption or penetration through a lesion to be effective. A very potent steroid is necessary if there is lichenification or hyperkeratosis, or if the inflammatory changes are predominantly within the dermis. These include clobetasol propionate 0.05% (Dermovate) and diflucortolone valerate 0.3% (Nerisone Forte). Potent preparations include betamethasone 0.1% (Betnovate) and triamcinolone acetonide 0.1% (Adcortyl), moderately potent preparations include clobetasone butyrate 0.05% (Eumovate) and mild preparations include hydrocortisone 1%.

Patients will have anxieties about applying potent topical corticosteroids, particularly because some of the patient information with the packaging advises against their use in the genital area. This can be reduced by giving the patient written instructions on their use, either as an information sheet or in a letter with specific instructions for the patient.

Long-term use of potent corticosteroids does have side-effects which include the development of telangiectasia, striae, thinning of the skin, increased hair growth and mild depigmentation. However, clinical experience finds that this is rare for vulval applications, and is more likely when large amounts are spread over the buttocks or inner thighs. There is a risk of worsening infection if steroids are applied where yeast or fungal organisms are present. Systemic absorption is rarely seen. Side-effects can be reduced by using less potent preparations where possible. However, it is better to use more potent steroids to gain relief and then reduce either

the potency or the frequency of application to maintain control. Sudden cessation will often produce a rebound of symptoms. A 30 g tube of Dermovate, if used appropriately [i.e. one application using a fingertip length (approximately 0.5 g) as squeezed from the tube] should last between 3 and 6 months.

On nights when topical steroids are not being applied or during the day, emollients can be applied to soothe and smooth the surface and to act as a moisturizer. Some emollients must be used with care in certain patients, such as those who have a history of irritation with wool, as components [e.g. wool fat (lanolin) or preservatives] can cause sensitization. Examples of emollients include aqueous cream BP, E45, Sudocrem, Ultrabase and Unguentum Merck (creams); Diprobase (cream or ointment); and emulsifying ointment BP, zinc and castor oil ointment BP (ointments). Some of these are suitable as soap substitutes (emulsifying ointment, aqueous cream), or preparations such as Alphakeri, Balneum or Oilatum can be added to the bath or shower (but can make the bath or shower dangerously slippery for the unsuspecting).

Dermatoses

While dermatologists will have little difficulty in reaching a diagnosis with these lesions, most gynaecologists are likely to be less certain. One of the confusing issues is the interchangeable use of the terms 'eczema' and 'dermatitis'; essentially they mean the same thing. Dermatitis is found in 64% of patients with chronic vulval symptoms (Fischer et al 1995). Many of these patients will have skin manifestations elsewhere and will be identified by history and examination. The term 'atopic dermatitis' is used when there is clinical evidence of atopy (e.g. asthma, hayfever or allergic rhinitis in the patient or immediate family). In some cases, biopsy and histology will be diagnostic. Many lesions will respond to topical corticosteroids, although the required potency will depend on the diagnosis.

Contact and irritant dermatitis

Contact dermatitis occurs as an allergic response to various allergens including topical antibiotics, anaesthetic and antihistamine creams, deodorants and perfumes (e.g. Balsam of Peru as used in various haemorrhoid creams), lanolin, azo-dyes in nylons, biological washing powders, spermicides, latex of sheaths or diaphragms, etc. An increasing number of referrals to vulval clinics are being seen because of the current trend to remove vulval hair. Some women have applied depilatory creams or waxes with subsequent irritant reaction, while others have inflicted skin damage by shaving.

Clinically, there is a diffuse erythema and oedema with superimposed infection or lichenification. Patch testing may identify the allergen to allow removal or avoidance of the factor, and moisturizing cream or mild steroids should provide local control. Haverhoek et al (2008) reported that 81% of the patients that they saw with vulval pruritus had at least one contact allergen detected on patch testing.

Some topical preparations will cause irritation over time (i.e. in a chronic fashion). The vulval appearances will be less obvious, with minimal erythema but with pallor or

pigmentation, and with dryness, thickening and cracking — lichenification, or lichen simplex chronicus. Lichen simplex chronicus (previously known as 'neurodermatitis') occurs in normal skin which becomes thick and fissured in response to the trauma of constant scratching. Lichenification is a similar change which is superimposed on another pathology such as dermatitis. These lesions are not usually symmetrical and occur in vulval areas accessible to scratching.

Treatment consists of the use of emollients or topical corticosteroids of low-to-moderate potency. Sometimes, sedation at night is useful to stop nocturnal scratching. Once control is gained, assessment for an underlying cause or lesion is often necessary.

Psoriasis

Psoriasis may occur exclusively on the vulva, but often there are lesions elsewhere and a family history. It affects approximately 2% of the population. Unlike psoriatic lesions elsewhere on elbows, knees and scalp, they are unlikely to show the hyperkeratotic silvery scales but are often salmon-pink in appearance with a sharp but irregular outline and with satellite lesions. Vulval psoriasis is treated with mild or moderately potent topical corticosteroids.

Lichenoid lesions and vulval intraepithelial neoplasia

Terms such as 'ichthyosis', 'leucoplakia', 'kraurosis', 'lichen planus sclereux' and 'dystrophy' have created confusion in describing vulval lesions (Ridley 1988). The current terminology has evolved from the ISSVD's 1976 classification of hyperplastic dystrophy, lichen sclerosus (no longer with 'et atrophicus') and mixed dystrophy; the abandonment of the term 'dystrophy' (MacLean 1991); and the use of the term 'non-neoplastic epithelial disorder of vulval skin and mucosa' (Ridley et al 1989) which included lichen sclerosus, squamous cell hyperplasia (formerly hyperplastic dystrophy) and other dermatoses. This did not cover those lesions with neoplastic potential or association, and the latest terminology incorporates 'differentiated vulvar intraepithelial neoplasia' for those lichenoid lesions with basal atypia and a significant association with vulval cancer (Sideri et al 2005, Scurry and Wilkinson 2006). This new terminology has met opposition, firstly because it removes the VIN 1, 2 and 3 classification which sat comfortably with CIN 1, 2 and 3 of the cervix, and replaces it with a single-grade system VIN (which groups together VIN 2 and 3 plus differentiated VIN). VIN 1 is uncommon compared with CIN 1. There is no evidence that it is a cancer precursor, and it is best considered as a warty lesion with no need for treatment and follow-up as one would do for the former VIN 2 and 3 lesions. The VIN frequently associated with HPV is now known as 'usual or classic type' (sometimes divided into basaloid and Bowenoid or warty subtypes, but this is not always meaningful because both subtypes are linked with HPV 16, and both appearances can occur in the same vulva). On the other hand, atypia or abnormality confined to the basal layer of lichen sclerosus (previously designated 'hyperplastic/hypertrophic or mixed dystrophy with atypia' may appear consistent with VIN 1 but has a significant association with

vulval carcinoma, and thus differentiated VIN is regarded as high grade (Jeffcoate and Woodcock 1961, Leibowitch et al 1990, Scurry et al 1997). There are opinions that differentiated VIN is only found in the immediate vicinity when vulval cancer develops within an area of lichen sclerosus, but also a growing awareness of the basal cell changes (e.g. overexpression of *p53*, *Ki-67* and *CD1a*) (Mulveny and Allen 2008) to provide the diagnosis in biopsies taken when cancer is not coexistent. Such cases are believed to have a greater risk of progressing to invasive cancer than cases with lichen sclerosus alone. Eva et al (2008) reported that there is an almost four-fold higher risk of recurrence when vulval cancer occurs in association with differentiated VIN.

Lichen sclerosus

The importance of lichen sclerosus is that it is common, occurring in at least one in 800 girls (Powell 2006) and increasing to one in 30 elderly women (Leibovitz et al 2000). It accounts for up to one-quarter of women seen in vulval clinics (MacLean et al 1998), 1.7% of patients seen in general gynaecological practice (Goldstein et al 2005) and 0.3–1 per 1000 of all new patients seen in a general hospital (Wallace 1971). It occurs in men, where it is known as balanitis xerotica obliterans, but at approximately one-sixth to one-tenth of the incidence in women. It is an inflammatory dermatosis and is frequently symptomatic, causing pruritus, sleeplessness, dyspareunia and constipation. It may produce major architectural changes and alteration in vulval appearance and function, and has a small but important risk of cancer; 60–70% of vulval squamous cell cancers occur against a background of or in association with lichen sclerosus. Lichen sclerosus involves the pudendum, either partially or completely as a figure-of-eight lesion encircling the vestibule and involving the clitoris, labia minora, inner aspects of the labia majora and the skin surrounding the anus. It is usually bilateral and symmetrical. It does not involve the vestibule or extend into the vagina or anal canal.

The lesions consist of thin, pearly, ivory or porcelain white crinkly plaques. Sometimes, there is marked shrinkage and absorption of the labia minora, coaptation of the labia across the clitoris to form a phimosis, and narrowing of the introitus to obscure the urethra and make intercourse impossible. Scratching will produce lichenification or may produce epidermal erosion and ulceration. Areas of ecchymoses and subsequent pigmentation are common. Lichen sclerosus may also involve the trunk or limbs in 18% of patients (Meyrick-Thomas et al 1988).

The histological features of lichen sclerosus typically show epidermal atrophy, dermal oedema, hyalinization of the collagen and subdermal chronic inflammatory cell infiltrate. There is a correlation between clinical appearance and histology, with the clinically thin area showing marked epidermal thinning with loss of rete ridges and vacuolation of the basal cells, while thick white fissured areas will histologically show hyperkeratosis, parakeratosis (abnormal keratinization) acanthosis and elongation, widening and blunting of the rete ridges (lichen sclerosus with lichenification; Ridley 1988). The inflammatory infiltrate may extend into the superficial dermis. These histological features are often modified secondary to trauma, with the presence of red blood cells or haemosiderin. However, histological changes

may be minimal, and the histology may appear normal in some clinically obvious cases.

Cause of lichen sclerosus

The aetiology of lichen sclerosus remains unknown. Its uneven distribution between countries raises the possibility of an infectious cause (e.g. *Borrelia burgdorferi* spread by tick bites), but while there has been demonstration of these spirochaetes (Aberer and Stanek 1987), subsequent studies have not supported this theory.

The possibility of a hormonal (androgen-associated) cause has been examined without conclusive results (Friedrich and Kalra 1984, Kohlberger et al 1998). There is recognition that the incidence is higher among postmenopausal women, but no evidence that it is due to oestrogen deficiency. Young girls with lichen sclerosus seem to gain symptom improvement at puberty, but one study has documented that 75% of these teenagers have persistent features of lichen sclerosus (Powell and Wojnarowska 2002).

The suggestion that lichen sclerosus might be related to an autoimmune process is supported by finding associations with other autoimmune manifestations, a family history of autoimmune-related disease in first-degree relatives or the presence of circulating autoantibodies in patients with lichen sclerosus (Goolamali et al 1974, Meyrick-Thomas et al 1988). Recently, circulating basement membrane zone antibodies have been found in the serum of patients with lichen sclerosus (Howard et al 2004), and a specific circulating autoantibody to extracellular matrix protein 1 (ECM1) has been described (Oyama et al 2003). The nature of ECM1 epitopes in the serum of patients with lichen sclerosus has been examined, and an enzyme-linked immunosorbent assay has been developed which is highly sensitive and specific for lichen sclerosus, and discriminates between lichen sclerosus and other disease/control sera (Oyama et al 2004). Higher anti-ECM1 titres correlated with more longstanding and refractory disease and cases complicated by carcinoma. The factors that initiated this antibody are unknown, or its appearance may predate the development of lesions or symptoms. Investigation of the inflammatory process has demonstrated oxidative damage to lipids, proteins and DNA in biopsies taken from untreated patients with lichen sclerosus (Sander et al 2004). Interferon- γ has been demonstrated within lesional epidermis, underlying dermis and the zone of inflammation, along with other cytokines including tumour necrosis factor- α , interleukin-1 α , IL-2 receptor CD25, intercellular adhesion molecule α 1 CD11a and ICAM-1 ligand ICAM-1 (Farrell et al 2006).

Some supportive evidence for a genetic cause has been described (Marren et al 1995), and a link with human leukocyte antigen (HLA) DQ7 has been demonstrated (Tasker and Wojnarowska 2003). Gao et al (2005) reported an increased frequency of DRB1*12 (DR12) and the haplotype DRB1*12/DQB1*0308/04/08/010, and a lower frequency of DRB1*0301/04 (DR17) among 187 women with lichen sclerosus, suggesting that HLA DR and DQ antigens or their haplotypes are involved in susceptibility and protection from lichen sclerosus.

Treatment of lichen sclerosus

Most dermatologists and gynaecologists now use topical steroids, such as clobetasol, and bland emollients to treat

lichen sclerosis (Tidy et al 1996). However, it is only relatively recently that the effectiveness of topical steroids has been confirmed (Dalziel et al 1989, 1991, Lorenz et al 1998, Sinha et al 1999). Most patients will respond to nightly applications within a few weeks, but treatment can be continued for 1 month followed by alternate nights for the second month and twice weekly in the third month. A fingertip amount (approximately 0.5 g) is applied each time, and a 30 g tube of clobetasol should last for 3 months (Neill et al 2002). If patients do not improve, coexisting fungal infection, sensitization to the cream or coexisting carcinoma must be considered.

Renaud-Vilmer et al (2004) used a similar protocol for 83 women with lichen sclerosis, and calculated that the estimated incidence of remission at 3 years was 72% in women under 50 years of age, 23% in women aged 50–70 years and 0% in women over 70 years of age. The incidence of relapse was estimated to be 50% at 16 months and 84% at 4 years, and age was not a factor in relapse rate. Thus, discontinuation of treatment is likely to lead to a return of symptoms. Cooper et al (2004) reported on 327 patients managed in Oxford; 96% had symptom improvement with treatment (66% complete responses and 30% partial responses). Among the 253 patients who had clinical appearances recorded, 23% showed a total response with return to normal colour and texture, 68% showed a partial response, 7% showed a minor response and 2% showed a poor response.

Patients with squamous hyperplasia are less likely to respond (Clark et al 1999), but longer use or very potent steroids might be more successful. There is no advantage in applying oestrogen cream or testosterone ointment to the vulva.

Physical destruction by cryotherapy or laser ablation of areas of lichen sclerosis no longer seems justified, and nor is vulvectomy. Very occasionally, it may be necessary to divide labial or preputial adhesions.

Relationship between lichen sclerosis and vulval squamous cell carcinoma

This relationship continues to be an area of debate, and the positive side of the argument has been presented elsewhere (MacLean 1993, 2000a). Several authors have reported a prevalence of carcinoma of 2.5–5% in women who present with lichen sclerosis (Friedrich 1985, Meyrick-Thomas et al 1988). It is unlikely that the development of malignancy led to the appearance of lichen sclerosis, although many of these women denied having had symptoms for any duration. Nevertheless, there are individual cases or series of cases that document carcinoma occurring some time after a clinical diagnosis of lichen sclerosis, in spite of the use of appropriate clobetasol therapy. Jones et al (2004) reported that women who develop cancer with lichen sclerosis are more likely to show clinical evidence of squamous hyperplasia, and are more likely to have been symptomatic for 5 years or more (Jones and Joura 1999). Cooper et al (2004) reported that six women developed carcinoma in spite of treatment in their series. Renaud-Vilmer et al (2004) reported that among eight women who developed cancer, one had discontinued treatment 3 years earlier, and a second patient had used treatment irregularly.

There are concerns that certain treatments may increase the risk of cancer. There have been publications advocating

the application of tacrolimus or pimecrolimus as alternatives to steroids, but following reports of apparently rapid progression to cancer, the US Food and Drug Administration released a warning advising caution with their use (Edwards 2008).

Many vulval cancers have lichen sclerosis in the adjacent skin, and the changes have been studied for various molecular alterations including changes in tumour suppressor gene activity and increased expression of mutant *p53* (Kagie et al 1997, Kohlberger et al 1995), and allelic imbalance with loss of heterozygosity or allelic gain (Pinto et al 2000). The authors' group have identified a mutation in codon 136 of exon 5 for *p53* found in the areas of invasion and also in the adjacent lichen sclerosis (Rolfe et al 2003). Several patients with lichen sclerosis plus hyperplasia have progressed to carcinoma, and it is suggested that immunohistochemical staining of increased expression of *p53* and *Ki-67* may be a useful predictor of progression before invasion occurs (Rolfe et al 2001).

Until we have a better way of anticipating which patients with lichen sclerosis are at greatest risk of developing cancer, it is recommended that any patient who has difficulty with symptom control should be referred to a specialist/specialist clinic. This includes women who require topical potent corticosteroid application three or more times a week, or who use more than 30 g clobetasol in 6 months for symptom control. Women with clinical evidence of localized skin thickening/hyperkeratosis require biopsies. If the skin contains differentiated VIN or other features of concern, a short intensive course of topical treatment should be followed by review biopsies. Persistent areas of differentiated VIN require excision. Particular care is needed in the follow-up of patients who have already been managed for cancer, because their chance of recurrence is higher than for other patients with lichen sclerosis (Jones et al 2008).

The following mnemonic may be helpful when assessing lichen sclerosis:

- Labial changes (e.g. reduction or fusion)
- Introital changes (e.g. narrowing)
- Clitoral changes including phimosis
- Hyperkeratosis
- Elevated or eroded areas
- Neoplastic or suspicious area with hyperkeratosis or contour changes
- Symptom control
- Colour, usually with pallor but also ecchymoses
- Localization, usually central
- Extension posteriorly, causing anal symptoms and constipation
- Rest of body; involvement elsewhere
- Other autoimmune conditions or associated symptoms
- Sexual difficulties
- Urinary difficulties
- Steroid use and misuse

Lichen planus

The lesions of lichen planus may be seen on mucous membranes or on cutaneous surfaces such as the inner surfaces of the wrists and lower legs. These cutaneous lesions are usually red or purple flat-topped nodules, or papules with an overlying white lacy-patterned appearance.

Involvement of the vulva is usually with white patterned areas that are sometimes elevated and thickened (hyper-trophic lichen planus), or may appear red and raw with features of erosion. Changes in the mouth are often seen. The vulval lesions may extend into the vagina where scarring, stenosis and adhesions make intercourse painful or impossible. In a small number of cases, 'crossover' from lichen sclerosus (involving the vulval skin) to lichen planus (involving the vestibule and vaginal mucosa) occurs.

Histology will show liquefactive degeneration of the basal epidermal layer, long and pointed rete ridges, with parakeratosis, acanthosis and a dense dermal infiltrate of lymphocytes close to the dermal epidermal margin. Immunohistochemistry shows differences in the expression of interleukin-4 and interferon- α between lichen planus and lichen sclerosus (Carli et al 1997).

When the condition is severe, treatment can be difficult, requiring systemic steroids, azathioprine or other immunemodifying agents. Lesser symptoms, particularly those externally on the vulva, can be managed with the application of topical corticosteroids; vaginal lesions can be managed with Colifoam (hydrocortisone) or Predfoam (prednisolone). Rarely, vulval cancer will arise in association with lichen planus (Dwyer et al 1995, Zaki et al 1996).

Paget's disease of the vulva

This is an uncommon lesion with uncertain malignant potential. Its appearance is of an eczematoid lesion with a scaly surface but vague margins, or it may be sharply bordered with a red and velvety texture, with areas or islands of hyperkeratosis. Histology classically shows large round atypical cells with oval nuclei and pale cytoplasm, singly or within clusters among the basal cells of the epidermis. These cells stain positively with cytokeratin 7, PAS para-aminosalicylic and CEA carcinomaembryonic antigen, and are regarded by many as carcinoma *in situ*. Their origin is uncertain. Their similarity to Paget's cells seen in the nipple, usually with underlying breast carcinoma, questions their association with cancers. Studies of large numbers of vulval Paget's cases report that less than 10% of cases will have an underlying adenocarcinoma of the vulva arising from an adnexal structure, and another 20% or more will have a carcinoma arising from adjacent viscera including rectocolon, endocervix or endometrium, ovary, urinary tract or breast. Wilkinson and Brown (2002) have proposed a classification that separates the lesions into those where the Paget's lesion is *in situ* without any associated cancer, those with an underlying adenocarcinoma of a skin appendage or a subcutaneous gland, and those that are secondary to an underlying anorectal adenocarcinoma, a urothelial cancer or an adenocarcinoma arising from elsewhere (this latter group may be suspected by finding cytokeratin 20 expression in the Paget's lesion). A small number of cases appear to progress from *in situ* to invasive adenocarcinoma if left untreated or undertreated.

Treatment by surgery is complicated with difficulty with primary closure, and plastic and reconstructive surgical techniques will be required. Achieving clear excision margins is difficult, and even when frozen section or definitive histology suggest clearance, recurrence will occur in 50% of cases or more. Currently, there is some enthusiasm for using

topical imiquimod, although series are small and follow-up is short (MacLean 2000b, MacLean et al 2004).

Vulval Pain/Vulvodynia

Vulval pain is a common complaint in specialist vulval clinics, with many women complaining that other doctors have either dismissed their symptoms or been unable to make a diagnosis or treat the condition effectively. However, the lack of clarity in the diagnostic categories reflects the complexity of the problem and the relative paucity of pathophysiological research in this area of medicine. Women with vulval pain are referred to genitourinary medicine, gynaecology, dermatology, urology, psychosexual medicine, physiotherapy and many other services. There are relatively few dedicated vulval clinics in the UK, and the majority exist to manage dermatoses and premalignant conditions, such as lichen sclerosus and VIN, rather than vulval pain.

Classification

The classification of vulval pain syndromes has been as difficult and confusing as vulval disorders in general; however, the most recent ISSVD classification logically uses a descriptive, anatomical and historical method. Vulval pain is not a single entity, and a detailed history and careful examination must be made before diagnosis is attempted. Vulval pain has been described in the medical literature for over 100 years (Skene, 1880). Previous definitions of these symptoms have referred to vulvar vestibulitis syndrome or burning vulvar syndrome, and to dysaesthetic vulvodynia. However, the lack of clarity in the diagnostic categories reflects the complexity of the problem, and the relative paucity of pathophysiological research in this area of medicine. Pain is described as either primary or secondary, provoked or unprovoked, and located anatomically, i.e. vestibulodynia, clitorodynia or the more generalized vulvodynia (Moyal-Barracco and Lynch 2004).

Pain characteristics

The predominant characteristic of vulval pain is a burning sensation. This can be accompanied by a description of 'rawness' or 'soreness'. Provoked pain with entry dyspareunia as the primary complaint is usually described as a burning pain, and may be accompanied by superficial splitting or fissuring at the fourchette. The burning sensation may last several hours or even days after attempted intercourse. Similar pain may be associated with tampon insertion or withdrawal.

Unprovoked vulval pain is described as a constant unremitting sensation of pain, characteristically a burning or raw sensation that is not exacerbated by contact.

In clinical practice, there is inevitably a crossover of provoked and unprovoked pain, with women either having an element of 'background' pain or developing a complex pain syndrome with both provoked and unprovoked elements. Using the anatomical site of pain as a descriptor allows careful clinical examination, and will improve understanding of other urogenital pain syndromes such as interstitial cystitis.

Management

In younger women, the predominant symptom of dyspareunia is more commonly a secondary provoked vestibulodynia. Attempted coitus is accompanied by severe pain at entry that has a burning character and splitting of the skin at the fourchette. The pain may last for several hours or even days after contact. The appearance of the external vulval skin is normal, but there is a band of erythema in the vestibule; pressure from a cotton bud over the vestibular gland openings causes severe pain (Q-tip tenderness). This pressure can be quantified using an algesiometer, but is most often judged clinically (Eva et al 1999). It is helpful to define any triggers for this syndrome, particularly candida or bacterial vaginosis infections, or urinary tract problems. Local anaesthetic gel can be used on a cotton ball to 'desensitize' as well as to allow coitus to continue. Some patients respond to topical steroids, possibly because their symptoms are due to an underlying dermatosis. Pain-modifying drugs such as pregabalin, gabapentin or amitriptyline may be beneficial, particularly in longstanding pain or when there is a mixed picture of provoked and unprovoked pain. Increasingly, biofeedback techniques are utilized, ranging from pelvic floor physiotherapy (Glazer et al 1995) to cognitive behavioural therapy. Rarely, surgical removal of the vestibular skin is the treatment of choice. Reports of this procedure in the 1990s suggested a high level of success, but long-term follow-up data are less convincing. It should, however, not be dismissed as an option.

Unprovoked vulvodynia is rarely a primary complaint and is more common in older women. The characteristic burning is unremitting and is not influenced or exacerbated by contact. It is equated to other pain syndromes such as trigeminal neuralgia, and these patients may themselves have more than one pain syndrome. Treatment is with one or a combination of the pain-modifying agents amitriptyline, gabapentin or pregabalin.

The treatment of vulval pain requires a sympathetic, professional approach. The consultation needs to be long enough for the complex history to be explored fully and for patients' anxieties to be discussed. Providing a diagnosis, no matter how limited, is reassuring. Simple measures such as advising the use of soap substitutes, managing precipitating factors and prescribing local anaesthetic gel are helpful. It may be worth considering physical therapies as described, but some women find using a transcutaneous electrical nerve stimulation machine beneficial. The use of pain-modifying agents means that patients must have clear advice about side-effects. It can be very helpful to work with colleagues in pain clinics, particularly in cases where there is clear evidence of pudendal neuropathy or in those cases where a combination of techniques is deemed necessary.

For a proportion of women, there is no resolution of pain despite all attempts at treatment. These women and many others require psychological support, and those that benefit from treatment may benefit from psychosexual counselling. Very little is known about how vulval pain affects partners, but anecdotally, couples report gaining benefit from counselling service. Women should be told about the patient support groups available in order to have the opportunity to talk to others similarly afflicted.

Vulval Ulceration

Vulval ulceration may be infective, aphthous or associated with Behçet's syndrome, Stevens-Johnson syndrome, dermatitis artefacta, benign mucous membrane pemphigoid, familial benign chronic pemphigus (Hailey-Hailey disease), pyoderma gangrenosum, Crohn's disease, histiocytosis X or toxic epidermal necrolysis (Lyell's syndrome). These conditions are uncommon, but may be serious or even fatal. Sometimes, the diagnosis can be made clinically or with a good history. However, occasionally, biopsy will be necessary and may require immunofluorescent techniques.

Vulval Infection

Some lesions will be due to primary infection, while in other cases, a lesion has become secondarily infected. The commensal flora of the vulva consists of staphylococci, aerobic and anaerobic streptococci, Gram-negative bacilli and yeasts. Increased temperature, humidity and lower pH of vulval skin make it more susceptible to infection compared with skin elsewhere.

Fungal infections

Genital candida infection is caused by the yeast *Candida albicans* in the majority of cases. Occasionally, non-albicans species or yeasts such as *Saccharomyces cerevisiae* are identified, and these should be considered if there is limited response to the usual antifungal therapies. Candida are frequently found within the vagina, but incidence is increased with pregnancy, the use of oral contraceptives, the concurrent use of broad-spectrum antibiotics, the presence of glucosuria or diabetes mellitus, and in association with the wearing of nylon underwear and tights. Fungal infections are less likely to be seen in postmenopausal women unless they are diabetic or immunocompromised, and other causes of pruritus should be sought. Infection produces acute vulval pruritus associated with a crusting discharge, and white plaques will be seen within the vagina and on the vulva. With more extensive infection, the vulva will become acutely erythematous with oedema and superficial maceration. Culture on appropriate medium or direct microscopy will demonstrate the presence of fungus or hyphae.

Treatment of simple infection may be with a topical imidazole preparation (topical nystatin seems to have been discontinued). More extensive or recurrent infections can be treated with fluconazole 150 mg capsule as a single dose and repeated 1–2 weeks later, or itraconazole 200 mg morning and evening for 1–3 days.

Tinea cruris is relatively uncommon in females but may be transmitted from a partner; appropriate enquiry may be rewarding.

Genital warts

These are known as condylomata acuminata and are caused by HPV types 6 and 11 in the majority of cases. Descriptions of the role of oncogenic or high-risk HPV can be found in Chapter 38. Such lesions may involve not only vulval skin but also the vagina and the cervix, and may extend around

the perianal area or out on to non-genital skin. Typical lesions are elevated with epithelial proliferation, usually discrete but sometimes confluent and covering large areas. The typical lesion shows koilocytosis in the upper third of the epithelium, acanthosis, parakeratosis, dyskeratosis and basal hyperplasia. The majority of condylomata acuminata are diploid, and only 10% may show nuclear atypia of various degrees, requiring differentiation from VIN with associated viral changes. The transmission of this virus is usually by sexual contact. The diagnosis is usually made on clinical appearance.

The treatment of single or small numbers of condylomata consists of the application of 25% trichloroacetic acid followed by 25% podophyllin at weekly intervals. This combination should be applied to the lesion and the patient asked to bathe some 6–8 h later to remove any excess. Prolonged application can lead to excessive skin excoriation. Podophyllin should not be used during pregnancy. Those condylomata that are resistant to such treatment can be treated with imiquimod or some form of physical therapy. Atypical or resistant condylomata should be biopsied in order to exclude verrucous carcinoma.

Due to the widespread distribution of HPV and the difficulty in eradicating this virus from genital skin of immunosuppressed women, it may not always be appropriate to apply repeated, painful treatments that damage the vulval skin. For some, the repeated use of imiquimod may be useful. It is hoped that, in the future, the use of the quadrivalent vaccine, which will provide immunity against HPV 6 and 11, will reduce the clinical load from condylomata. Unfortunately, the recently introduced bivalent vaccine for British teenage girls is unlikely to prevent HPV 6 and 11 infection.

Herpes simplex

Vulval herpes lesions are usually associated with type 2 herpes simplex virus rather than type 1. The primary episode is associated with an incubation period of some 2–20 days, with an average of 1 week. There is often an associated prodromal illness before a localized area of vulval skin becomes erythematous, followed by the appearance of blisters and subsequent ulceration. These lesions are usually acutely painful and may be associated with inguinal lymphadenitis. Vulval discomfort associated with micturition may cause urinary retention. Secondary bacterial infection can occur. Resolution of discomfort and healing occurs some 7–14 days after the onset of symptoms. Frequently, the primary infection is much less dramatic. Following the primary episode, the virus enters the dorsal ganglia where it becomes dormant or latent. Reactivation may occur and a secondary episode results. Recurrences are less painful than primary lesions and rarely last more than 48 h.

The diagnosis and management of vulval herpes can be found in Chapter 63.

Bacterial infections

Bartholinitis

This is the most common bacterial infection of the vulva. It is usually found between menarche and menopause, but is not necessarily associated with sexual activity. It results from

infection of the duct leading from the gland. Obstruction of the duct will produce an abscess in the acute situation, or a cyst if infection is low grade or recurrent. Causative organisms may be from the vulval flora or may be sexually transmitted.

The management of bartholinitis requires appropriate swabs for bacteriology, analgesia, antibiotics and surgical drainage of a cyst or abscess by marsupialization. In women over 40 years of age, the edges of the cyst should be sent for histological examination to exclude carcinoma.

Staphylococcal infection

This may take the form of perifolliculitis, involving the hair follicles and adjacent glandular structures within the dermis, or furunculosis which are larger, deeper lesions involving subcutaneous tissue that eventually discharge through multiple sinuses. Occasionally, staphylococcal impetigo is seen. Management consists of the application of povidone iodine washes or mupirocin ointment, or use of an antistaphylococcal antibiotic such as flucloxacillin. Occasionally, surgical drainage of the pus is required.

Hidradenitis

Similar features of recurrent staphylococcal infection are seen with hidradenitis suppurativa, a chronic inflammatory disease involving the apocrine glands (Thomas et al 1985). This condition is more likely to involve the axilla but will occasionally involve the vulva, perianal areas or the genitofemoral fold. These abscesses are deep and may often involve anaerobic organisms. Acute cases will require intravenous antibiotics such as flucloxacillin and metronidazole, and may require surgical deroofting of the abscess. Long-term antibiotic treatment may be combined with hormone control of apocrine gland activity. This appears to be best achieved using a combination of oestrogen and cyproterone. There is a small risk of carcinoma developing in areas of chronic scarring.

Other bacterial infections

Streptococcal infection of the vulva may be relatively superficial or localized, as in erysipelas. This will be associated with sharply defined erythema, oedema and pain. Streptococci may cause deeper infection involving tissue down to the fascia or periostium. Gangrene of the skin (necrotizing fasciitis) may complicate any form of vulval surgery, especially in diabetic women. High doses of penicillin are required. In cases with deep infection, other aerobic and anaerobic organisms are often involved, and a combination of antibiotics and very wide surgical excision is required. Infection of the vulva with *Neisseria gonorrhoeae* is rare in adults. The urethra, however, will be infected in approximately 75% of cases of gonorrhoea, and this may lead to infection of periurethral glands. Involvement of the duct of Bartholin's gland is described above. Gonococcal vulvitis can occur in children.

Other bacterial infections involving the vulva include erythrasma, trichomycosis, tuberculosis (lupus vulgaris), syphilis, chancroid, granuloma inguinale and lymphogranuloma venereum, and is described in Chapter 63.

Protozoal and parasitic infections

Trichomonas vaginalis

This involves the vagina initially, although the patient may present with vulval symptoms. This infection is due to *Trichomonas vaginalis*, a flagellated protozoan, and is associated with vaginal discharge (which is often frothy and brown or green), vaginal irritation and dyspareunia. The organisms may be identified in a wet film by their motility or may be recognized in cervical smears. Colposcopic assessment of the vagina shows characteristic double-looped coarse punctation of the vagina and cervix, which may be diffuse and extensive or patchy and localized (strawberry vagina). Treatment of this infection is with metronidazole 200 mg three times a day for 7 days or a single 2 g dose. The partner should be treated concurrently and both should be warned not to take alcohol with this antibacterial agent.

Threadworms

Enterobius vermicularis live in the large bowel, lay eggs on the anal margins and cause pruritus ani; vulval irritation may also occur. The ova can be recognized on microscopy of a strip of Sellotape left in position overnight. Treatment is with piperazine or mebendazole.

Other infections that may involve the vulva include pediculosis (crabs), scabies, amoebiasis, schistosomiasis, filariasis and leishmaniasis. Vulval lesions due to entamoeba, schistosoma, filarial worms and leishmania are uncommon in Western countries. They should be considered in anyone returning from overseas, and may cause diagnostic difficulties if considering a 'tropical' venereal infection or even syphilis.

Benign Tumours of the Vulva

Lipomas and fibromas are the most common benign tumours of the vulva which arise from other than the epithelial tissues. Haemangiomas are benign tumours composed of blood vessels, with the capillary type (strawberry haemangioma) being most commonly encountered in infants and young children. A variety of site-specific stromal tumours can occur in the vulvovaginal area, including aggressive angiomyxoma, angiomyofibroblastoma and cellular angiofibroma (McCluggage 2009). In young to middle-aged women, fibroepithelial stromal polyps occur more frequently in the vagina, but also in the vulva or cervix. They are benign and are lined by normal squamous epithelium, which may be keratinized depending on the location; the stroma varies from bland to cellular and pleomorphic, especially in pregnancy-associated cases. There is potential for local recurrence, particularly if incompletely excised.

Angiomyofibroblastoma is a well-circumscribed lesion which occurs almost exclusively in the vulvovaginal region, and is often clinically thought to be a cyst of Bartholin's gland. The stromal cells may have an epithelioid appearance and tend to cluster around vessels; they show reactivity for vimentin and desmin, and are actin negative.

Cellular angiofibroma occurs exclusively in the vulva of middle-aged women, and behaves in a benign fashion. It is composed of spindle cells arranged in short fascicles in a

meshwork of thick-walled vessels. The cells express vimentin but not desmin or actin.

Aggressive angiomyxoma is a locally infiltrative tumour that recurs in 30–40% of cases if incompletely excised. It occurs most commonly in the reproductive years and usually has a gelatinous appearance. Histologically, it is a myxoid, poorly cellular neoplasm composed of bland spindle cells which merge imperceptibly into the surrounding stroma. There is no specific immunohistochemical marker, although high mobility group AT-hook2 HMGA2 expression may be useful.

Superficial angiomyxoma arises in the dermis and subcutaneous tissue, and therefore often appears polypoid. If multiple lesions involving other sites are present, Carney's complex may be suspected and further investigations are warranted to exclude a cardiac myxoma.

Prepubertal vulval fibromas have been described which may be a childhood variant of aggressive angiomyxomas or may be enlargement secondary to hormonal changes approaching puberty. Superficial myofibroblastoma of the female lower genital tract may involve the vulva, vagina or cervix, are usually polypoidal or nodular, and are benign in behaviour (McCluggage 2009). Other smooth muscle tumours of the vulva are much rarer than the uterine counterpart; the presence of mitotic activity, nuclear pleomorphism or an infiltrative margin is associated with locally recurrent potential (atypical smooth muscle tumours), while tumours with any three of the following features are considered sarcomas: more than 50 mm in size, infiltrative margins, more than five mitoses/10 High-Power Fields, and moderate to severe atypia.

Granular cell tumours are of peripheral nerve sheath origin and arise in the vulva of children or adults as painless subcutaneous nodules of the mons pubis, labia majora or clitoris. They are often associated with pseudoepitheliomatous hyperplasia of the overlying epithelium, and are composed of epithelioid, granular cells infiltrating the stroma and typically exhibiting S-100 protein. Wide local excision is the treatment of choice. Neurofibromas may affect the vulva as part of von Recklinghausen disease. Benign angiokeratoma may be difficult to distinguish from a melanoma, especially if the initial red colour has given way to the later brown or black hue, and the lesion has started to bleed due to trauma.

Squamous papillomata and 'skin tags' are common, benign and similar in appearance. They may be solitary or multiple (vestibular or squamous papillomatosis, micro-warts). They lack significant correlation with HPV DNA and histology may overestimate viral changes.

Seborrhoeic keratosis may also occur on the hair-bearing skin of the vulva of elderly women. The rare keratoacanthoma might well be mistaken for invasive squamous cancer because of its rapid growth over a matter of weeks. Spontaneous involution usually begins after approximately 6 months. The centre of this well-demarcated, regular dome contains a plug of keratin, which may suggest the diagnosis, but complete excision of the lesion is required for histological confirmation.

Vaginal Infection

Between puberty and the menopause, the presence of lactobacilli maintains a vaginal pH of between 3.8 and 4.2; this

protects against infection. Before puberty and after the menopause, the higher pH and urinary and faecal contamination increase the risk of infection. Normal physiological vaginal discharge consists of transudate from the vaginal wall, squames containing glycogen, polymorphs, lactobacilli, cervical mucus, residual menstrual fluid and a contribution from the greater and lesser vestibular glands.

Vaginal discharge varies with hormonal levels and does not automatically mean infection. Non-specific vaginitis may be associated with sexual trauma, allergies to deodorants or contraceptives, or the chemical irritation of topical antimicrobial therapy. Infection may be aggravated by the presence of foreign bodies, continuing use of tampons and the presence of an intrauterine contraceptive device.

Vaginal infection may produce vulval symptoms, and the above descriptions of genital candidiasis, trichomoniasis, herpes simplex virus, HPV and syphilis are relevant to vaginal lesions. *Neisseria gonorrhoeae* will not infect the vaginal epithelium, except in prepubertal girls or postmenopausal women. If there is suspicion of sexual abuse in a young girl, an appropriate vaginal swab should be taken.

Bacterial vaginosis

Bacterial vaginosis is now believed to be due to a vibrio or comma-shaped organism named *Mobiluncus*. Other organisms, including anaerobes, may have a contributory role. These organisms are believed to be sexually transmitted, although the condition may be due to imbalance in the vaginal ecosystem. Usually, the vagina is not inflamed and therefore the term 'vaginosis' is used rather than 'vaginitis'. Nearly half of 'infected' patients will not have symptoms (Thomason et al 1990), while others will complain of increased or unpleasant discharge, soreness and irritation.

Examination will reveal a thin, grey-white discharge and a vaginal pH greater than 5. A Gram stain of the discharge will show 'clue cells' which consist of vaginal epithelial cells covered with micro-organisms. The absence of lactobacilli will be confirmed if a characteristic fishy amine smell is released when a drop of vaginal discharge is added to saline on a glass slide, along with one drop of 10% potassium hydroxide. The diagnosis is made if three of these four criteria are met.

There are claims that bacterial vaginosis is associated with increased risk of preterm labour (Hay et al 1994), pelvic inflammatory disease and postoperative pelvic infection (Paavonen et al 1987, Eschenbach et al 1988). The treatment of bacterial vaginosis is metronidazole, either as 400 mg two or three times a day for 7 days or as a single 2 g dose. Alternatively, clindamycin 2% can be used as a vaginal cream but, unlike metronidazole, this is active against lactobacilli and will delay the restoration of normal vaginal flora.

Toxic shock syndrome

This topic has been included here because it is associated with the use of vaginal tampons during menstruation or less frequently in the puerperium (Shands et al 1980). Although there is a link between this syndrome and certain organisms (e.g. group A streptococci and *Staphylococcus aureus*) found within the vagina of affected women, it is not a vaginal infection. The manifestations are usually systemic with occasionally life-threatening consequences. Removal of

superabsorbent brands of tampons from the market in the USA, and greater care in tampon use and insertion reduced the frequency of the syndrome. Early effective treatment of hypovolaemia in severe cases is essential. Treatment is the same as for septicaemia, and includes intravenous fluids and inotropic support where necessary. The cause should be eliminated where possible, and a β -lactamase-resistant penicillin should be given parenterally. Further attacks can occur and it is recommended that tampons should not be used until *Staphylococcus aureus* has been eradicated from the vagina.

Other Vaginal Pathology

Atrophy

This is seen following the menopause, but can also occur prior to puberty and during prolonged lactation. Examination shows loss of rugal folds and prominent subepithelial vessels, sometimes with adjacent ecchymoses. The patient may present with vaginal bleeding, vaginal discharge, or vaginal dryness and dyspareunia. Superficial infection, with Gram-positive cocci or Gram-negative bacilli, may be associated.

Treatment requires oestrogen to restore the vaginal epithelium and pH. This is usually by topical oestrogen cream or pessary. Systemic absorption will increase blood levels of oestrogen. Alternatively, hormone replacement therapy can be used.

Trauma

A torn hymen following a first attempt at intercourse may result in profuse, frightening haemorrhage. Suture of the bleeding vessel under general anaesthesia should be accompanied by one or more radial incisions in the hymen to prevent recurrence.

Trauma in young girls or women may be the result of falling astride an object like a bicycle or fence. It may result from sexual abuse, sometimes self-inflicted, but may represent sexual assault or rape. It may also occur following normal sexual intercourse, particularly in a postmenopausal woman who has not had intercourse for some time. In these cases, the laceration is usually at the vault of the vagina in the posterior fornix.

An indwelling catheter may be necessary and ice packs will give some comfort. Damage to the vagina, rectum, urethra, bladder or ureter may also occur. Pain relief with opiates and replacement of blood loss may be needed urgently. Examination under anaesthesia is often required to determine the extent of the damage. A closed haematoma is best managed conservatively, but bleeding lacerations will require suture. Devitalized tissues will need to be excised, and tears in bowel or bladder must be repaired in layers.

Seminal fluid allergy

Patients may present with a history of dyspareunia with itching, burning or swelling, or occasionally more widespread symptoms such as urticaria, bronchospasm or even angioneurotic oedema, after intercourse. The allergic reaction appears to be due to sensitization to seminal fluid

(Poskitt et al 1995). Symptoms may arise following first coitus or after exposure to several sexual partners.

Treatment has included long-term immunotherapy following skin testing (Friedman et al 1984). Treatment with desensitization may be helpful, and antihistamines and intravaginal cromoglycate are described (Poskitt et al 1995).

Sjogren's syndrome

Patients with vaginal dryness and pain may have Sjogren's syndrome if there is ocular or oral dryness. They may have arthralgia, myalgia or Raynaud's phenomenon. The diagnostic criteria include ocular and oral symptoms, ocular signs, salivary gland histology, other evidence of salivary gland involvement and the presence of autoantibodies. Vaginal symptoms may predate the oral or ocular symptoms.

Benign Tumours of the Vagina

Tumours in the vagina are uncommon. Condylomata acuminata are by far the most common type seen. The frond-like surface is usually characteristic, but it is wise to await the result of a biopsy before instituting treatment.

Endometriotic deposits may be seen in the vagina. They are most common in an episiotomy wound and may lie deep to the epithelium.

Simple mesonephric (Gartner's) or paramesonephric cysts may be seen, especially high up near the fornices. If asymptomatic, they are best left untreated. If treatment is required, marsupialization is effective and safer than excision. Similarly, management of anterior wall cysts must include the exclusion of a bladder or urethral diverticulum.

Adenosis (multiple mucus-containing vaginal cysts) is a rare condition which, even more rarely, gives rise to symptoms. A variety of abnormalities are reported in the daughters of women who took diethylstilboestrol during their pregnancy. Most of these are of no significance (see Chapters 38 and 39).

Female Circumcision/Genital Mutilation

It is inevitable that obstetricians and gynaecologists will encounter patients with female genital mutilation (FGM), and management will sometimes cause more harm than good. Gordon et al (2007) emphasized that reversal procedures are better performed in non-pregnant or antenatal patients, rather than when the patient presents in labour and is dealt with by junior or inexperienced staff.

The World Health Organization (http://www.who.int/topics/female_genital_mutilation/en/) has defined FGM as all procedures involving partial or total removal of the external female genitalia, or other injury to the female genital

organs for non-medical reasons. FGM is classified into four types, as follows.

- Type I: partial or total removal of the clitoris and/or prepuce (clitoridectomy).
- Type II: partial or total removal of the clitoris and labia minora, with or without excision of the labia majora (excision).
- Type III: narrowing of the vaginal orifice with creation of a covering seal by cutting and appositioning the labia minora and/or the labia majora, with or without excision of the clitoris (infibulation).
- Type IV: all other harmful procedures to the female genitalia for non-medical purposes; for example, pricking, piercing, incising, scraping and cauterization.

Most of the cases described by Gordon et al (2007) and managed in North London were of type III and the clitoris was found intact after reversal.

It is estimated that more than 2 million women and children undergo some form of FGM each year, mainly in Africa, but also in the Middle East and Asia. It is a cultural rather than a religious requirement or duty. Performing FGM in the UK became illegal in 1985, and in 2003, it became an offence for UK citizens to perform FGM in other countries. Nevertheless, many young girls appear to leave the UK to have the procedure performed between their birth and reaching puberty. Acute complications include pain, infection, bleeding, injury to the urethra/vagina/rectum, urinary retention, faecal incontinence and death. More chronic complications include urinary and menstrual difficulty, haematocolpos, sexual difficulty if not impossibility from fibrous scarring, and epidermoid cysts. Incompetent attempts at defibulation have caused urethral and rectal injuries, further scarring and persistent dyspareunia.

As mentioned above, Gordon et al (2007) advocated reversal as an elective procedure rather than during labour. If it is performed during labour, the fused labia minora should be incised in the midline anteriorly as far as the urethral meatus, and further anterior dissection of clitoral structures should be deferred because of risk of urethral damage and difficult haemostasis. It is illegal to close the infibulations following delivery, even if the husband insists. When performed electively, the CO₂ laser provides a bloodless incision, but care must be taken of underlying structures. Examples have been seen where careless use of electrodiathermy has left damage to underlying clitoral glands when dissecting a paraclitoral epidermoid cyst.

Gordon et al (2007) emphasized the requirement of providing an interpreter and nurse/midwife who will meet the psychosexual and social aspects of FGM. Certainly, the scenario of a patient presenting in advanced labour with undisclosed infibulated labia and the threat of imminent tearing should be avoided.

KEY POINTS

1. A multidisciplinary team approach to vulval disease is helpful.
2. The presenting symptoms will not indicate the nature of the pathology.
3. Topical steroids are effective and safe in the treatment of many vulval disorders.
4. Topical oestrogens have little to offer the woman with a vulval disorder.
5. There is no place for vulvectomy in the management of lichen sclerosis.

Introduction

Vulval cancer is an uncommon condition that largely affects elderly women (Figure 41.1). The Office of National Statistics recorded 842 cases in 2005 (Office of National Statistics 2008). This incidence of 3.3 per 100,000 ranks vulvar cancer as the 20th most common cancer in women. The most recent mortality figures recorded 270 deaths for all age groups, giving a death rate of 1.05 per 100,000 women (0.53/105 persons), ranking it the 19th most common cause of cancer death in women.

The changing population demographics will result in an increase in the incidence of the disease as a result of an ageing population, and an increase in the associated comorbidity, providing additional medical challenges to effective multimodality care.

The disease is potentially curable in most cases, even in the elderly and unfit. However, if the diagnosis is delayed or if managed inappropriately, the outcome is variable with the potential for a miserable, degrading death. Effective surgical treatment seems deceptively simple, but few gynaecologists and their nursing colleagues acquire sufficient experience of this disease to offer the highest quality of care for these women. This is a disease where there is a compelling case for centralized care, and where one might expect the reorganization of gynaecological cancer services to benefit women significantly.

Aetiology

There seem to be two distinct types of vulvar carcinoma: the first type occurs predominantly in older women, is typically a well-differentiated keratinizing tumour that is not associated with usual-type vulvar intraepithelial neoplasia (VIN) or human papilloma virus (HPV) infection, but which often shows adjacent epithelial disorders such as lichen sclerosis and/or differentiated VIN; and a second type which mainly occurs in younger women, is associated with usual-type VIN, shows evidence of oncogenic HPV infection, and may be associated with synchronous or metachronous squamous preneoplastic or neoplastic lesions of the cervix, vagina and anal canal (Crum et al 1997, van der Avoort et al 2006). Smoking may be an important cofactor involved in the aetiology of HPV-related vulvar tumours (Hussain et al 2008).

Case-controlled studies have failed to confirm an association with diabetes mellitus, obesity, vascular disease and syphilis.

The following are recognized risk factors for all types of vulval cancer:

- immunosuppression;
- advanced age;
- history of cervical neoplasia (Ansink and Heintz 1993);
- lichen sclerosis (4–7% risk of developing cancer) (MacLean and Reid 1995, Meffert et al 1995);

Figure 41.1 Age distribution of vulval cancer.

Source: Office of National Statistics 2008 Cancer Statistics Registration, Registration of Cancer Diagnosed in 2005, England. Series MB1 No. 36. Her Majesty's Stationery Office, London.

Figure 41.2 The histological subtypes of vulval cancer.

- VIN and multifocal disease (5–90%) (Herod et al 1996, Jones et al 1997);
- Paget's disease (Fishman et al 1995);
- melanoma in situ (Bradgate et al 1990, Ragnarsson-Olding et al 1993); and
- smoking (Hussain et al 2008).

Histology

The majority of vulvar cancers (90%) are squamous in origin (Figure 41.2). Verrucous and basal cell cancers are squamous cell variants.

Non-squamous cancers include Bartholin's gland cancer and other adenocarcinomas, malignant melanoma, Paget's disease and sarcomas. The vulva may also be a site for lym-

phoma and metastases from elsewhere (Finan 2003). Rarely, primary breast cancers have been reported (Piura et al 2002).

The histology has a bearing on management, largely because of the different risks of nodal metastases and the predilection for distant spread.

Lymphatic Drainage

An understanding of the lymphatic drainage is important as the regional nodes are a potential site of metastases.

Lymph drains from the vulva to the superficial inguinal glands and then to the deep femoral glands in the groin. Drainage continues to the external iliac glands. Drainage to both groins occurs from midline structures — the perineum and the clitoris — but some contralateral spread may take place from other parts of the vulva (Iversen and Aas 1983). Direct spread to the pelvic nodes along the internal pudendal vessels occurs very rarely, and no direct pathway from the clitoris to the pelvic nodes has been demonstrated consistently. An important aspect of the lymphatic drainage is the concept of sentinel nodes in each groin. This is the first node that draining lymph encounters as it drains bilaterally from the vulvar basin (Cabanas 1977). This anatomical concept has been exploited recently to develop selective lymphadenectomy in this disease.

Natural History of Squamous Cancers

Malignant transformation may occur in more than one site, and this appears to apply in both HPV-negative and -positive scenarios, although more commonly in the latter. The earliest recognizable phase of vulval cancer is termed 'superficially invasive disease' (stage Ia). The tumour is less than 2 cm in lateral dimension, and there is less than 1 mm invasion when measured from the base of an adjacent dermal papilla. Accurate identification and classification of this stage requires expert pathological interpretation, and is exceptionally important as the current consensus would suggest a virtually negligible risk of lymph node metastases. As the cancer gradually increases in size and progressively invades the deeper layers of the dermis, it spreads locally. The tumour will eventually involve the local lymphatics, hence the propensity for groin lymph node involvement (Table 41.1).

Local progression will eventually lead to involvement of adjacent structures. The urethra, anus and vagina can all become involved. In advanced stages, there can be extensive local destruction and involvement (often with superadded infection), groin node metastases and potentially lymph node involvement in the pelvis, para-aortic and neck nodes. Metastases in adjacent skin may also be noted, and haematogenous spread can also occur in late disease.

If widespread disease is seen with small vulvar tumours, a more aggressive histotype may be present, such as a melanoma or sarcoma.

Presentation

The medial aspects of the labia majora are the most common sites for disease to develop (70%). The labia minora, clitoris,

Table 41.1 Groin recurrences in women who did not undergo any form of groin node surgery. None had clinically suspicious lesions in the groin, and all were regarded as 'low-risk cases'. In many, groin node surgery was omitted because of associated medical problems

Lesion					
Reference	Depth (mm)	Diameter (cm)	n	Groin recurrences	Deaths due to groin disease
Magrina (1979)	5	2	35	4	3
Hacker et al (1984a)	>1	2	23	2	2

			128	19 (14%)	

NK, not known.

periurethral areas, posterior fourchette and perineum account for the remainder (30%). Small lesions may be asymptomatic and go unnoticed by the patient. However, both Hacker et al (1981) and Monaghan (1990) have commented that, in a significant minority of patients, there appears to be considerable delay in presentation. The intimate nature of the disease, fear and/or ignorance and the advanced age of many patients might partly explain this observation. The fact that the disease is uncommon may also be contributory, as primary carers may not recognize the significance of symptoms or fail to recognize the clinical signs. Whatever the cause, a significant number of cases continue to present in advanced stages.

The reasons for presenting have been analysed by Podratz et al (1983a). Pruritus is the most common presenting symptom (71%), and an ulcer or mass will have been noted in nearly 80% of cases. Surprisingly, pain is only a feature in 23% of cases. Bleeding (26%), discharge (13%) and urinary tract dysfunction (14%) are other common reasons for presentation.

Assessment

The assessment of these women should include confirmation of the diagnosis, an assessment of disease extent, and an holistic approach to the patient to assess relevant comorbidity and/or other factors that may impact on the management plan.

Examination

The character, size and location(s) of all lesions should be documented. Particular attention should be paid to assess any involvement of the vagina, urethra, bladder base or anus. Palpation is important to determine possible involvement of the surrounding bony structures. Discomfort and tenderness may necessitate an examination (and biopsies) under general anaesthesia. The groin should be examined, although a negative assessment cannot reliably exclude cancer. Hard, enlarged, fixed or ulcerated nodes (Figure

41.3) need to be documented as this will almost certainly influence management.

Due to the potential for other genital tract malignancies, the vagina and cervix should also be assessed thoroughly and biopsied as necessary.

Diagnosis

Diagnosis is based upon a representative biopsy of the tumour. The biopsy should include an area where there is a transition from normal to malignant tissue (Figure 41.4). Biopsies should be of a sufficient size to allow differentiation between superficially invasive tumours and frankly invasive tumours, and orientated to allow quality pathological interpretation. Radical excision should not be undertaken without prior biopsy confirmation of malignancy unless there are extenuating circumstances.

The histopathological report should include:

- site;
- size (in three dimensions);
- associated features (such as the presence of VIN or condylomata);
- tumour type;
- depth of invasion;
- maximum horizontal measurement;
- whether the tumour is completely excised and tumour-free margin measurement;
- presence or absence of lymphovascular invasion; and
- nature of the adjacent non-malignant squamous epithelium.

The grading of the tumour is based on the percentage of undifferentiated cells, with grade 1 having no undifferentiated cells, grade 2 having less than half undifferentiated cells and grade 3 having more than half poorly differentiated cells.

Staging

There are two staging systems: the Tumour, Node, Metastasis system and the International Federation of Gynaecology and

Figure 41.3 Enlarged fungating lymph node.

Figure 41.4 Diagnostic 'wedge biopsy' to include tumour and adjacent 'normal' epithelium.

Obstetrics (FIGO) system. Most gynaecologists use the latter which, since its last update in 2000, is based upon clinical and surgical findings. Table 41.2 details both staging systems.

Prognostic Factors

The size of the primary tumour and the status of the regional lymph nodes are the only two factors that have been consistently associated with outcome (Homesley et al 1991). The 5-year survival rate in cases without lymph node involvement is in excess of 80%, falling to less than 50% if the inguinal nodes are involved and 10–15% if the iliac or other pelvic nodes are involved.

Tumour size

Tumours larger than 2 cm in diameter have a greater chance of being frankly invasive and metastasizing to lymph nodes.

Table 41.2 FIGO staging of vulvar cancer

FIGO stage	Description
I	Tumour confined to the vulva
Ia	Lesions ≤ 2 cm in size, confined to the vulva or perineum and with stromal invasion ≤ 1 mm. No nodal metastasis
Ib	Lesions > 2 cm in size or with stromal invasion > 1 mm confined to the vulva or perineum. No nodal metastasis
II	Tumour of any size with extension to adjacent perineal structures (lower 1/3 urethra; lower 1/3 vagina; anus) with negative nodes
III	Tumour of any size with or without extension to adjacent perineal structures (lower 1/3 urethra; lower 1/3 vagina; anus) with positive inguino-femoral nodes
IIla	(i) With 1 lymph node metastasis (≥ 5 mm), or (ii) 1–2 lymph node metastasis(es) (< 5 mm)
IIlb	(i) With 2 or more lymph node metastases (≥ 5 mm), or (ii) 3 or more lymph node metastases (< 5 mm)
IIlc	With positive nodes with extracapsular spread
IV	Tumour invades other regional (upper 2/3 urethra; 2/3 vagina) or distant structures
IVa	Tumour invades any of the following (i) Upper urethral and or vaginal mucosa; bladder mucosa; rectal mucosa or fixed to pelvic bone, or (ii) Fixed or ulcerated inguino-femoral lymph nodes
IVb	Any distant metastasis including pelvic lymph nodes

FIGO, International Federation of Gynaecology and Obstetrics.

Depth of invasion

Invasion less than 1 mm (superficially invasive or stage Ia) has a negligible risk of lymph node involvement, and groin node dissection may be omitted (Hacker et al 1984b). The risk of nodal metastasis rises to 8% for a depth of 1–2 mm, 11% for 2–3 mm, and over 25% for lesions with a depth greater than 3 mm (Morrow et al 1993) (Figure 41.5).

Lymphovascular space permeation

This factor along with tumour border pattern (infiltrating vs pushing) and perineural invasion are not included in the surgicopathological staging of vulvar cancer, although they are associated with an increased risk of metastasis (Heaps et al 1990, Hopkins et al 1991).

Lymph node status

This is the most important prognostic variable. The number of lymph nodes involved and the nature of involvement influence the prognosis. Microscopic involvement of a single groin node, without extracapsular involvement, represents a low risk of recurrence, and adjuvant therapy is not necessary (Hacker et al 1983). Conversely, multiple nodal diseases and macroscopic and/or capsular involvement are indications for adjuvant radiotherapy in order to reduce the risk

0mm	0%
1mm	8%
2mm	11%
3mm	25%

Depth Nodal risk

of groin recurrence, which is usually fatal (van der Velden et al 1995). It is well recognized that groin node dissection is associated with significant morbidity. Almost 50% of patients undergoing groin node dissection will suffer post-operative complications, most commonly wound infection, wound breakdown and lymphoedema (Gaarenstroom et al 2003). For these reasons, a presurgical investigation that could identify those at risk could have a significant therapeutic benefit. Assessment by clinical palpation of the groins is inadequate; of patients with clinically normal lymph nodes, 16–24% have metastases, while 24–41% of those with clinically involved nodes are negative when examined histologically (Sedlis et al 1987, Homesley et al 1993). Even though the majority of vulvar cancers are still assessed clinically, there is increasing interest in utilizing additional imaging, particularly of the regional node groups. Ultrasonography, computed tomography (CT), magnetic resonance imaging (MRI) and positron emission tomography have all been assessed but lack the sensitivity to exclude microscopic disease reliably (Selman et al 2005). Sentinel node sampling (vide infra) has shown promise, and the collective experience of this technique now suggests that it is reliable, at least in early-stage disease.

Sentinel lymph node detection

The concept of the 'sentinel lymph node' (SLN) was introduced in 1977 by Cabanas (1977). He defined the SLN as the first node in the lymphatic basin that receives primary lymphatic flow. Subsequent studies have confirmed that a tumour-free SLN implies absence of lymph node metastases in the entire draining lymphatic basin (Balega and van Trappen 2006). The last two decades have seen the technique become established in the management of cutaneous melanoma and breast cancer. The concept (Figure 41.6) has now been introduced for the management of early vulvar cancers, and the published performance data to date are promising (Table 41.3).

There are two ways to detect the SLN: blue dyes and radioactive tracer. Both are injected around the edge of the tumour prior to surgery; they are complementary and combining these techniques achieves a higher sensitivity compared with a single tracer. Excised SLNs are subjected to frozen section analysis and ultrastaging. Full inguino-femoral lymphadenectomy is avoided if SLNs are negative. Since unrecognized groin disease is nearly always fatal, the negative predictive value of this method is of particular concern. Early studies

Figure 41.6 Diagrammatic illustration of the sentinel node concept.

included full inguino-femoral lymphadenectomy following the SLN procedure to provide a 'gold standard' for comparison. The results confirmed a negative predictive value approaching 100%.

A large-scale international trial, the Groningen International Study on Sentinel Nodes in Vulvar Cancer (GROINSS-V), was established to test the safety and clinical utility of SLN dissection in early-stage vulvar cancer. This was an observational study. Patients with stage I and II disease with tumour size less than 4 cm were recruited. Only patients found to have disease in either SLN underwent full inguino-femoral lymphadenectomy. Among 259 patients with unifocal vulvar cancer and a negative sentinel node, groin recurrences occurred in six (2.3%) women, and the 3-year survival rate was 97%. This result was comparable with similar historical groups of patients that had full inguino-femoral lymphadenectomy. However, both short- and long-term morbidity were significantly reduced, including shorter hospital stay and less wound breakdown and lymphoedema (van der Zee et al 2008). The authors thus proposed that sentinel node dissection should be the standard treatment for patients with unifocal early-stage vulvar cancer. In the second phase of the GROINSS-V study, investigators are evaluating radiotherapy, rather than complete inguino-femoral lymphadenectomy, in patients with metastatic SLNs. The objective is to further reduce morbidity by avoiding double-modality treatment.

Treatment

Factors influencing the management plan

Site of the tumour

Centrally located tumours lie close to midline structures such as the clitoris, urethra, vagina and anus, and are associated with a higher risk of bilateral inguinal nodal spread compared with more lateral tumours. If the medial margin

lies within 1 cm of the midline, they should be defined as central (de Hullu and van der Zee 2006). Bilateral groin node dissection is recommended for central tumours, and ipsilateral groin node dissection is recommended for lateralized tumours (Figure 41.7). Furthermore, if central tumours approximate to the urethra or anal canal such that these structures would be sacrificed to achieve satisfactory clearance, urinary or bowel diversion may be necessary.

Surgery

Surgery is the mainstay of treatment. The traditional ‘butterfly’ incision en-bloc radical (Figure 41.8) vulvectomy introduced by Taussig (1940) and Way (1960) clearly improved survival. The excised tissues included the vulvar lesion, the inguinofemoral lymph nodes and the lymphat-

ics in between. Large areas of normal tissue were frequently included, and primary wound closure was rarely achieved. Protracted postoperative recovery and severe wound complications and disfigurement were associated with this procedure. This postoperative morbidity has been the main driver for progress over the last two decades. Surgical treatment has become more individualized and conservative, aimed at reducing morbidity without compromising survival.

Separate incisions

The use of three separate incisions for groin dissections and vulvectomy instead of the traditional ‘butterfly incision’ has improved wound healing and reduced the frequency of wound breakdown (Hacker et al 1981). The suggestion that

Figure 41.8 En-bloc radical vulvectomy.

this lesser approach might result in an increase in skin bridge recurrence was not born out in a Cochrane review, which showed a skin bridge recurrence rate of less than 1% (Ansink and van der Velden 2000). The hypothesis underpinning this strategy is based upon the belief that in early tumours, cells disseminate by embolization rather than in continuity (Willis 1973); therefore, there should be no residual tumour in the lymphatic channels between the tumour and the groin nodes. Reported cases of skin bridge recurrences were mainly seen in women with large groin node metastasis (Rose 1999). No prospective randomized controlled studies have been performed comparing the traditional radical vulvectomy with en-bloc inguino-femoral lymphadenectomy with the separate incision technique. However, de Hullu et al (2002) did undertake a retrospective comparison and noted a significant increase in groin and skin bridge recurrence with the less radical procedure (6.3% vs 1.3%, $P=0.029$). This, however, did not result in a difference in overall survival. They concluded that in view of the morbidity of the 'butterfly incision' and relatively low skin bridge recurrence rate, separate incisions were the preferable technique for stage I and II disease.

Modified radical vulvectomy or wide local excision

The main factor causing severe morbidity and disfigurement following radical vulvectomy is the extensive dissection and removal of normal tissue from the vulvar region. In the last two decades, less radical surgery, such as modified radical vulvectomy, hemivulvectomy and wide local excision, has been introduced to reduce morbidity without compromising survival. Tumour-free margins are the most important predictive factor for local recurrences. Both Heaps et al (1990) and de Hullu et al (2002) showed that a tumour-free margin of more than 8 mm was associated with significantly lower local recurrence rate. These studies found that suboptimal tumour-free margins (<8 mm) were more likely when the

intentional macroscopic margin was 1 cm or less. A lesion might extend further than judged by macroscopic inspection, and tissues usually shrink during preparation for histological examination (Balega et al 2008). A macroscopic surgical margin of 2 cm is thus recommended. This may be difficult to achieve in some cases where the tumour is adjacent to the urethra and anus, but every effort should be made to maximize the margins. The tumour-free margins should be the same regardless of whether a radical vulvectomy or a wide local excision is performed.

Unilateral inguino-femoral lymphadenectomy

Lateralized vulvar tumours rarely metastasize to the contralateral inguino-femoral lymph nodes without the ipsilateral nodes being involved. van der Velden (1996) pooled 489 patients with unilateral vulvar cancers and found only 0.9% with isolated contralateral lymph node metastases in lateralized stage I disease. Similarly, Gonzalez Bosquet et al (2007) reviewed 320 patients who underwent bilateral groin lymph node dissection. Among 163 patients with unilateral vulvar lesions, only three (1.8%) had an isolated contralateral nodal metastasis. No patients with a tumour diameter equal to or less than 2 cm and depth of invasion less than 5 mm had bilateral groin lymph node involvement. Given the recognized higher morbidity and low numbers of patients with contralateral metastases, it is now a generally accepted practice to perform a unilateral inguino-femoral lymphadenectomy in patients with stage I and II lateralized tumours, without suspicious lymph nodes on palpitation. If nodal disease is found in one groin, the opposite groin should also be explored. Normal lymph flow may be disturbed in cases of ipsilateral groin node metastases with alternate channels developing, thus allowing contralateral spread.

Superficial inguinal lymphadenectomy

In order to reduce lymphoedema and wound breakdown associated with groin dissection, DiSaia et al (1979) proposed removing only the superficial inguinal lymph nodes lying anterior to the cribriform fascia, without exploration of the deeper femoral nodes. The rationale for this was that lymphatic drainage from the vulva passes first to the superficial inguinal nodes before subsequently draining to the femoral nodes. The superficial inguinal nodes were assessed by frozen section, and a deep dissection was performed if the superficial nodes were found to be positive. However, the results of subsequent studies have not been encouraging. Unexpected groin recurrences occurred in patients with early-stage disease and presumed negative inguinal nodes (Hacker et al 1984b, Kelley et al 1992, Stehman et al 1992a). The current practice is that a full inguino-femoral lymphadenectomy including all superficial inguinal lymph nodes and femoral lymph nodes medial to the femoral veins should be performed whenever there is an indication for node dissection.

Pelvic lymphadenectomy

Routine pelvic lymphadenectomy is no longer considered in the surgical management of vulvar carcinoma. The inci-

dence of pelvic node metastases is approximately 5% and is very rare in the absence of inguinofemoral lymph node metastases (Gadducci et al 2006). One randomized trial (Homesley et al 1986) compared pelvic lymphadenectomy with pelvic radiotherapy in patients with inguinofemoral lymph node metastases after radical vulvectomy and bilateral inguinofemoral lymphadenectomy. The 2-year survival rate for the radiation group was significantly better than that for the pelvic lymphadenectomy group (68% vs 54%, $P<0.03$). The incidence of groin recurrence was less in the radiation group (5.1% vs 23.6%, $P<0.02$). However, the rate of pelvic recurrence was increased in patients who received pelvic irradiation. It was postulated that radiation may not be able to sterilize bulky pelvic metastatic nodes. Therefore, removal of enlarged pelvic nodes seen on CT scan via an extraperitoneal approach was suggested before starting radiotherapy.

Surgical morbidity

Incremental reduction in the radicality of treatment has resulted in less morbidity. Wound breakdown, wound infections, lymphocysts, lymphoedema, vulvar disfigurement and psychosexual disturbance remain problematic.

Vulvar morbidity

Primary wound closure was often difficult if not impossible when the traditional 'butterfly incision' was used. This is still the case when large excisions are required, but even in these instances, more frequent use of plastic reconstructive techniques results in improved healing and better cosmetic outcomes. In smaller vulvar tumours, wide local excision with separate groin wounds has decreased the wound breakdown rate significantly.

Problems with micturition (spraying, angulation of urine, urethral stenosis) are not uncommon if the distal third of the urethra is excised. Surgery for perineal and perianal lesions may give rise to problems with defaecation (constipation, tenesmus and faecal incontinence), localized pain when sitting and coital difficulties (Barton 2003). Occasionally, repeat surgery is needed to excise fibrotic tissue or to widen the stenotic introitus in order to facilitate coitus.

Groin morbidity

Lymphocysts and infection are the two most common short-term groin complications. Despite the routine use of drains and antibiotics, complications are still as high as 66% (Gaarenstroom et al 2003). More troublesome is the long-term complication of lower limb lymphoedema, which is often difficult to treat and can cause significant distress to patients. The incidence of lymphoedema is further increased if adjuvant radiotherapy is given after surgery (Barton 2003). The simplest approach to reduce groin morbidity is less radical surgery and avoidance of double treatment. SLN dissection goes some way to addressing this need without compromising disease control, at least in early vulval cancer. The incidence of wound breakdown, infection and lymphoedema decreased to 11.7%, 4.5% and 1.9%, respectively (van der Zee et al 2008).

Psychological morbidity

Vulvar disfigurement, coital difficulties and lower limb oedema are all chronic problems that continually remind patients of their past disease and treatment. This can impact adversely on relationships and self-esteem. Leg oedema is distressing as it is a visible disfigurement, can reduce mobility and impact on independent living. Such complications may eventually result in depression, low self-esteem and loss of confidence. Consideration should be given to provide psychological and psychosexual support for these patients.

Radiotherapy

Radiotherapy was traditionally considered to have a limited role in the management of vulvar cancer. Vulvar skin does not tolerate irradiation well, especially so when orthovoltage equipment was in use. Vulvar skin is thin, delicate, very sensitive and highly vascularized. Radiotherapy to this area frequently causes both acute and chronic reactions, making treatment difficult to tolerate, particularly in the elderly. Acute inflammation with both dry and moist desquamation is very painful, and may be exacerbated by associated urinary incontinence. Tolerance of radiotherapy has improved with megavoltage therapy. Late reactions include scarring, fibrosis and telangiectasia causing functional compromise and cosmetic impairment.

Postoperative adjuvant therapy

Patients with risk factors for local recurrence, such as a close surgical margin, lymphovascular space permeation, poorly differentiated tumour grade or diffuse infiltrative growth pattern, should be considered for adjuvant external beam radiation therapy to reduce the risk of recurrence (Perez et al 1998, Blake 2003).

With regard to the nodal status, no additional treatment is recommended if there is only one microscopically positive lymph node (Hacker et al 1983). However, if two or more metastatic nodes are present, or there is capsular involvement in a single metastatic node, postoperative adjuvant radiotherapy is usually recommended (van der Velden et al 1995). In a subgroup analysis of Homesley et al's study, the survival advantage of radiotherapy was limited to those patients with clinically evident groin nodes or more than one positive groin node (Homesley et al 1986).

Neoadjuvant therapy

In order to achieve an adequate surgical margin with large tumours close to the urethra and/or anal canal, it may be necessary to compromise urethral and/or anal function with an associated diversion. In 1973, Boronow suggested a combined radiosurgical approach to shrink the tumour preoperatively, aiming to spare this group of patients from exenterative surgery. Subsequent reports (Hacker et al 1984a, Boronow et al 1987) confirmed the feasibility of this function-sparing approach. More recently, concurrent chemoradiation has been used with the same intent. Moore et al (1998) gave concurrent cisplatin/5-fluorouracil (5FU) and radiation therapy to 71 patients with stage III–IV disease. Thirty-three patients (46.5%) had no visible tumour

after chemoradiation, and only three patients were not able to preserve urinary and/or gastrointestinal continence after surgery. van Doorn et al (2006) reviewed the available literature and concluded that preoperative chemoradiotherapy reduces tumour size and improves operability. However, complications are considerable, especially in delayed wound healing, and overall increased treatment-related morbidity.

Primary treatment

Radiotherapy alone as a treatment for vulvar cancer is not recommended in operable tumours, mainly because of the perceived intolerance of vulvar tissue. However, it is an option in patients who cannot undergo surgery because of advanced disease or comorbidity issues. In selected cases, primary radiotherapy can cure vulvar cancer with acceptable morbidity (Busch et al 1999). Chemotherapy can be added to the regimen, either as a neoadjuvant to reduce tumour bulk or as concomitant chemoradiotherapy to improve cure rates (Moore et al 1998).

Although the groin tolerates radiotherapy better than the vulva, primary radiotherapy to treat groin disease is not recommended. One study has reported a higher recurrence rate when comparing radiation therapy with inguinofemoral lymphadenectomy (Stehman et al 1992b). However, this study has been criticized on the basis of suboptimal radiotherapy technique, particularly that the maximum dose did not reach the deep inguinofemoral nodes. More recently, Katz et al (2003) re-evaluated the value of primary radiotherapy for groin disease. Comparable recurrence rates were observed when radiotherapy alone was compared with inguinofemoral lymphadenectomy (15% vs 16.6%). The authors concluded that radiotherapy alone was as effective as surgery in preventing groin recurrence. This study was criticized largely because of difficulties in interpreting the individualized treatment. There were also doubts about the radicality of lymphadenectomy.

Although the available data are somewhat confused, radiotherapy appears to be an effective treatment for microscopic (residual) disease in the groin, but less effective when gross disease is present.

Palliation

Patients with advanced disease and distant metastasis might not derive much overall benefit from radical surgery. Radiotherapy may offer a palliative option in some of these cases.

Chemotherapy

The role of chemotherapy in vulvar cancer is either as concomitant therapy with radiation or as a palliative manoeuvre in recurrent or metastatic disease. Several cytotoxic drugs (cisplatin, methotrexate, bleomycin, mitomycin C and 5FU) have been shown to have activity when used alone or in combination (Shimizu et al 1990, Benedetti Panici et al 1993). 5FU appears to be the most effective agent. In a series of 12 patients with advanced vulvar cancer involving either or both the anus and urethra, a combination of cisplatin and 5FU gave a 100% response rate. The anal sphincter and urethra were conserved in these patients during subsequent

radical surgery. However, three patients receiving cisplatin alone showed no response or even progression (Geisler et al 2006). However, all of the studies were small and uncontrolled, and should be interpreted with caution.

Advanced Disease

Advanced vulvar cancer (T3/T4) is characterized by local extension to neighbouring structures (urethra, vagina, bladder and anus). Regional lymph node metastases are present in over 50% of these patients (Hacker et al 1983). Ultraradical surgery with urinary tract and/or bowel diversion is required for complete excision. Unfortunately, most of these patients are elderly and frail, having significant comorbidities rendering them unsuitable for such extensive surgery. Radiation therapy with or without chemotherapy can shrink some tumours before surgery, sparing them from stoma formation and reducing surgical morbidity (Hacker et al 1984a, Boronow et al 1987). Furthermore, preoperative chemoradiation can result in fixed groin nodes becoming resectable (Montana et al 2000). Radiation therapy with or without concurrent chemotherapy should be considered as an alternative option for patients with advanced vulvar cancer who would otherwise require exenterative surgery.

Recurrences

Rouzier et al (2002) identified three patterns of local recurrence:

- primary site recurrence, defined as within 2 cm of the vulvectomy scar (39%);
- recurrence remote from the primary tumour site, regarded as reoccurrence of cancer (39%); and
- skin bridge recurrence (22%).

Tumour size, surgical margins and depth of invasion (Rouzier et al 2002) are risk factors for primary site relapse. It is usually salvageable with repeat surgical excision or radiotherapy (Thomas et al 1989, Hopkins et al 1990). Local recurrence remote from the primary tumour site should be considered as a new primary lesion and is seen more frequently in patients with a background of lichen sclerosis or differentiated VIN. Again, surgical excision is the first choice of treatment. The prognosis is generally good, with more than 60% of patients surviving for more than 3 years. Patients with skin bridge recurrence seldom live for more than 1 year (Rouzier et al 2002).

Almost one-third of all recurrences occur in the groin. Groin recurrence is seen more often when previous node dissection was omitted, or when positive nodes were present at primary surgery. The prognosis is poor, with more than 90% of patients dying within 1 year (Hacker et al 1984b).

Malignant Melanoma

Malignant melanoma is the second most common vulvar malignancy, accounting for 5–10% of cases of vulvar cancer. The incidence is less than 0.2 per 100,000 women per year (Piura 2008). It is a disease of the elderly, occurring in the fifth to seventh decades, and is more common in

Caucasians. They usually present with a vulvar mass, bleeding and pruritus. The labia minora, clitoris or inner aspects of the labia majora are the most common sites. A variety of pigmented lesions mimic vulvar melanoma, including vulvar melanosis, different types of nevi and acanthosis nigricans. Biopsy is essential for diagnosis. Three histological subtypes have been described (Ragnarsson-Olding et al 1999a):

- lentiginous melanoma;
- superficial spreading melanoma; and
- nodular melanoma.

Up to 25% of tumours are amelanotic.

Various staging systems have been proposed for vulvar melanoma. The most commonly used are the Clark et al (1969), Breslow (1970) and Chung et al (1975) systems. However, in 1994, a Gynecologic Oncology Group study showed that the American Joint Committee on Cancer melanoma staging system is more accurate in predicting outcome (Phillips et al 1994).

Radical vulvectomy has been recommended for vulvar melanoma in the past. However, the available literature suggests no survival difference in patients having a radical vulvectomy, simple vulvectomy or wide local excision (Rose et al 1988, Tasseron et al 1992). The current consensus is to aim for a tumour-free margin of at least 1 cm for tumour less than 1 mm thick, a tumour-free margin of 2 cm for tumours 1–4 mm thick, and a tumour-free margin of at least 1 cm at the subcutaneous layer for all cases. The role of elective regional node dissection is controversial for both cutaneous and vulvar melanoma. A prospective study by the Gynecologic Oncology Group in 1994 failed to find a definite survival benefit for elective lymph node dissection in patients with vulvar melanoma (Phillips et al 1994). The role of adjuvant therapy for treatment of vulvar melanoma is also unclear. Radiotherapy has been suggested for incomplete tumour resection or positive groin/pelvic lymph nodes (Piura 2008). Interferon α -2b seems to be a promising adjuvant therapy for cutaneous melanoma (Kirkwood et al 2001), but data in vulvar melanoma are lacking.

Vulvar melanoma is usually highly aggressive, with a tendency to recur locally and spread haematogenously to distant organs such as the liver, lung and brain. Reported 5-year survival rates range from 21% to 54% (Podratz et al 1983b, Blessing et al 1991, Ragnarsson-Olding et al 1999b, Verschraegen et al 2001). As with cutaneous melanoma, the survival rate correlates with depth of invasion.

Bartholin's Gland Carcinoma

Primary carcinoma of Bartholin's gland is rare, accounting for 0.1–7% of all vulvar carcinomas (Nasu et al 2005). Bartholin's gland carcinomas may initially be confused with Bartholin's cyst or an abscess. The tumour may arise from either the gland or the duct, thus various histological types may occur, including adenocarcinomas, squamous carcinomas, transitional cell carcinomas, adenosquamous carcinomas and adenoid cystic carcinomas. Since most of these lesions are located deep in the vulva, radical excision usually involves removing part of the vagina, levator muscles and the ischio-rectal fat in order to achieve an adequate tumour-free margin. If regional groin or pelvic lymph nodes are

positive, adjuvant radiotherapy is indicated to reduce the risk of recurrence (Copeland et al 1986). Adenoid cystic carcinoma is a rare variant, characterized by slow growth, with a marked tendency for perineural and local invasion. The tumour seldom metastasizes and carries a better prognosis (Nasu et al 2005).

Invasive Paget's Disease

Paget's disease of the vulva is a rare intraepithelial neoplasia, probably originating from the vulvar apocrine glands. Approximately 10% of cases are invasive and 4–8% are associated with adenocarcinoma (Fanning et al 1999). The disease predominantly affects postmenopausal Caucasian women, usually presenting with vulvar pruritus and soreness. The lesion is usually multifocal, well demarcated and characterized by red eczematous patches (Figure 41.9). These originate on the hair-bearing regions of the vulva. Notoriously, vulvar Paget's disease extends beyond the macroscopic lesions, and recurrence frequently occurs despite a clear surgical margin obtained at wide local excision (MacLean et al 2004). Thus, it is not uncommon for patients to undergo multiple recurrences and re-excisions over years of surveillance. In the event of finding invasive carcinoma, the patient should be treated with radical vulvectomy and groin node dissection, as for squamous cell carcinoma.

An additional concern with extramammary Paget's disease is its association with other malignancies, including breast, uterine, vagina, bladder, pancreas, lung and stomach. Appropriate management includes investigations to try and exclude other cancers.

Verrucous Carcinoma

Verrucous carcinoma is a rare variant of squamous cell carcinoma, characterized by local invasion without nodal or distant metastases. The gross appearance resembles a giant condyloma. Histologically, there is an exophytic papillary component of well-differentiated squamous epithelium with hyperparakeratosis and well-demarcated

Figure 41.9 Recurrent Paget's disease after vulval excision.

pushing borders. The treatment is modified radical vulvectomy. Lymphadenectomy is not indicated (Finan 2003).

Basal Cell Carcinoma

Basal cell carcinoma accounts for approximately 2–4% of all cases of vulvar cancer. It usually appears as a small (1–2 cm), raised, nodular lesion with well-defined edges. Wide local excision with a 1 cm margin is usually curative, and recurrence and metastases are rare (Mulayim et al 2002).

Sarcoma

Vulvar sarcoma is extremely rare and treatment options are derived from anecdotal case reports. Leiomyosarcoma, rhabdomyosarcoma, malignant fibrous histiocytoma, dermatofibrosarcoma protuberans and epithelioid sarcoma are all reported in the literature. The usual treatment is radical vulvectomy and groin node dissection (Aartsen and Albus-Lutter 1994, Hensley 2000).

Cancer of The Vagina

Introduction

Vaginal carcinoma accounts for less than 2% of gynaecological cancers (Kirkbride et al 1995). In 2005, 216 cases were registered in the UK, equivalent to 0.8/100,000 women (Office of National Statistics 2008). Seventy percent of these patients were 60 years of age or older. Squamous cell carcinoma was the most common variant (Grigsby 2002). The evidence base is drawn from case reports and retrospective reviews.

Aetiology

The exact aetiology for primary vaginal cancer is unknown. Up to one-third of patients have a history of a cervical lesion, either benign or malignant (Peters et al 1985). Stock et al (1995) reviewed 100 cases of vaginal cancer and found that patients who had a previous hysterectomy were more likely to develop a lesion in the upper third of the vagina compared with women who had not had an hysterectomy (62% vs 34%, $P < 0.005$). Possible explanations for this are: occult residual disease from a cervical lesion, HPV as a persisting carcinogenic agent (Daling et al 2002), an effect of radiation therapy given for previous genital tract cancer may induce vaginal cancer, and the disease interval is usually more than 10 years (Chaturvedi et al 2007).

Similar to cervical cancer, there is a premalignant condition in the vagina, vaginal intraepithelial neoplasia (VAIN). However, the true malignant potential of VAIN is unclear. Vaginal cancer caused by chronic irritation, such as procidentia and vaginal pessaries, has been reported (Ghosh et al 2009) but the incidence is extremely low. Intrauterine exposure to diethylstilboestrol was thought to be a causative agent for clear cell adenocarcinoma of the vagina in the past (Herbst et al 1971). However, with the cessation of its use in the 1970s, it is rarely seen nowadays.

Pathology

More than 80% of primary vaginal tumours are squamous cell carcinomas; adenocarcinomas are the second most common, accounting for approximately 15% (Grigsby 2002). The remainder are sarcomas, malignant melanomas, small cell carcinomas, lymphomas and carcinoid tumours. Metastatic lesions from non-gynaecological sites have also been reported, including bladder, kidney, colon and rectum (Tarraza et al 1998, Parikh et al 2008).

Clinical assessment

The most common presenting symptoms are painless vaginal bleeding (81%) and abnormal discharge (33%) (Pingley et al 2000). Large, posteriorly sited tumours may cause tenesmus. When disease has spread beyond the vagina, patients may present with pelvic pain. Occasionally, vaginal cancer may be recognized after an abnormal Pap smear (Pride et al 1979).

The majority of lesions are located in the upper posterior vagina, usually in the form of an exophytic mass with contact bleeding (Pingley et al 2000). It is not uncommon to miss a small lower vaginal lesion at the initial examination, when it may be hidden by the blades of the speculum. If vaginal cancer is to be excluded, a full and thorough inspection of the entire vagina is required.

In order to make a diagnosis of vaginal cancer, apart from histological confirmation, certain criteria are to be met (Benedet et al 2000):

- the primary site has to be in the vagina;
- the lesion should not involve the uterine cervix, vulva or urethra, otherwise they should be considered as the likely primary cancer; and
- this is not a recurrence of genital tract cancer.

The diagnosis of vaginal cancer should only be made with a biopsy, which may be taken either in the office or under anaesthesia. The latter is preferable because it provides an opportunity to examine the patient in total relaxation, and a generous full-thickness excisional biopsy may be obtained. Cystoscopy and proctosigmoidoscopy are indicated when local spread is suspected. Chest radiography and an intravenous pyelogram are necessary to exclude lung metastasis and ureteric involvement. Cross-sectional imaging (CT scan or MRI) is useful in evaluate the extent of disease and intra-abdominal metastasis.

Staging

The FIGO staging system for vaginal cancer is shown in Table 41.4. It is a clinical staging system based on findings from physical examination, cystoscopy, proctoscopy and chest X-ray.

Pattern of spread

Vaginal cancer initially spreads by local invasion; it may infiltrate adjacent pelvic organs and the side walls by direct extension. Tumour in the upper vagina embolizes to the pelvic and para-aortic lymph nodes, while those in the lower vagina metastasize to the groin lymph nodes and

Table 41.4 International Federation of Gynaecology and Obstetrics (FIGO) staging for carcinoma of the vagina

FIGO stage	Description
Stage 0	Carcinoma in situ, intraepithelial carcinoma, high-grade vaginal intraepithelial neoplasia
Stage I	The carcinoma is limited to the vaginal wall
Stage II	The carcinoma has invaded the subvaginal tissues but has not extended on to the pelvic sidewall
Stage IIa	The carcinoma has invaded the subvaginal tissues but has not extended to the parametrium
Stage IIb	The carcinoma involves the parametrium but has not extended to the pelvic sidewall
Stage III	The carcinoma has extended to the pelvic sidewall
Stage IV	The carcinoma extends beyond the true pelvis or has clinically involved the mucosa of the bladder or rectum. Bullous oedema as such does not permit a case to be allocated to stage IV
Stage IVa	The carcinoma has spread to adjacent organs and/or direct extension beyond the true pelvis
Stage IVb	The carcinoma has spread to distant organs

secondarily to pelvic nodes. Haematogenous dissemination to distant organs is a late event.

Treatment

Due to the rarity of this disease, there is no consensus on the treatment, be it radiation or surgery. Patients should be managed in tertiary centres, and all treatment should be individualized according to stage and site of disease.

Radiotherapy is the most commonly used treatment modality for vaginal cancer. The close proximity of the bladder and rectum limit the ability of surgery to radically excise tumour without significant functional compromise. Exenterative surgery is often needed in order to achieve adequate margins, especially with lower vaginal tumours (Figure 41.10).

Both teletherapy and brachytherapy are used in managing these cancers. A number of reports have shown that sequential use of teletherapy followed by brachytherapy results in a better outcome (Perez et al 1999, Pingley et al 2000). External radiation is used to treat disease with lateral infiltration; the irradiation field is similar to that for cervical cancer. The pelvis receives 50 Gy, covering the side walls, pelvic nodes and the whole vagina (Grigsby 2002). The irradiation field should be extended to the groin if the tumour is located in the lower third of the vagina. External beam irradiation also results in shrinkage of large tumours, facilitating subsequent brachytherapy. Interstitial implants using premade templates may be indicated for deeply invasive tumours. Early-stage disease (stage I–II) may be treated by brachytherapy alone.

**Figure 41.10** Primary tumour of the lower third of the vagina.

Although surgery has a limited role in the treatment of vaginal cancer, it is indicated in certain situations. Stage I–II upper vaginal lesions can be treated surgically. Upper vaginectomy in combination with radical hysterectomy and bilateral pelvic lymphadenectomy can be performed for patients with an intact uterus. If the patient has had a hysterectomy, radical upper vaginectomy and pelvic lymphadenectomy may be considered. In a retrospective study of 89 stage I and II patients, Davis et al (1991) reported no survival differences when comparing surgery and radiotherapy.

Pelvic exenteration can be considered for localized recurrent disease after radiotherapy. It should also be considered in medically fit patients with stage IVa disease, especially in those with symptomatic fistulae.

There is limited information in the literature regarding concurrent chemoradiation therapy for vaginal cancer. The use of this modality of treatment for vaginal cancer is a logical extension of its use in cervical cancer.

Prognosis

Staging is the only consistent prognostic factor in predicting outcome. The 5-year survival rates for stage I, II, III and IV disease are 73%, 51%, 33% and 20%, respectively (Beller et al 2001).

Uncommon vaginal tumours

Rhabdomyosarcoma (sarcoma botryoides)

This rare tumour mainly affects children below 5 years of age. The polypoid tumour protrudes from the vagina, resembling a bunch of grapes. Treatment is based upon primary chemotherapy using vincristine, actinomycin D and cyclophosphamide plus doxorubicin, followed by conservative organ-sparing surgery or radiotherapy. Survival rates of over 80% are now achievable (Andrassy et al 1999, Harting et al 2004).

Clear cell adenocarcinoma

Approximately 15% of primary vaginal cancers are adenocarcinomas, predominantly affecting young women. In the main, they arise from vaginal adenosis, which is a consequence of disrupted Müllerian development. This malformation may or may not be related to in-utero diethylstilboestrol exposure (Herbst and Anderson 1990). The treatment is similar to that of squamous cell carcinoma of the vagina. However, every effort should be made to retain vaginal and ovarian function as most of these patients are still in their reproductive years.

Malignant melanoma

Primary malignant melanoma of the vagina constitutes less than 0.3% of all melanomas and less than 3% of malignant vaginal tumours (Siu et al 2004). It is highly malignant and is notoriously more aggressive than non-genital and vulvar melanoma. Most patients are diagnosed at an advanced stage with a deeply invasive tumour. The 5-year survival rate is 17%. Radical surgery does not appear any better than conservative surgery (wide local excision) in terms of survival (Reid et al 1989). Radiotherapy is mainly used as an adjuvant therapy to decrease recurrence.

KEY POINTS

1. Vulvar cancer probably arises through two oncogenic pathways: one related to oncogenic HPVs and the other related to lichen sclerosis.
2. It is predominantly a disease of the elderly and comorbidity is common.
3. Surgery is the mainstay of treatment and has become progressively less radical over time.
4. Management must always address the possibility of regional disease in the groin lymph nodes.
5. Sentinel node detection is likely to further reduce treatment-related morbidity for early vulvar cancer.
6. Multimodality treatment with reconstructive surgery should improve outcomes in more locally advanced disease.
7. Groin node dissection is not routinely required for vulvar melanoma as the depth of invasion is the most potent prognostic indicator.
8. The squamous variants, basal cell and verrucous carcinoma, have a very low risk of regional spread, and therefore do not require groin lymphadenectomy.

Introduction

Worldwide, approximately 200,000 women are diagnosed with endometrial cancer each year (Ferlay et al 2004). Of these, more than two-thirds arise in developed countries where age-standardized incidence is four times higher than in developing countries (Ferlay et al 2007). Endometrial cancer is now the most common gynaecological malignancy in Western Europe and North America, with an annual incidence of 81,500 women in the European Union and 40,100 women in North America. In the UK, the incidence of endometrial cancer increased by 29.3% between 1993 and 2005, with an incidence of 6891 women in 2005 (Office for National Statistics 2008). This increase is attributable to an increase in obesity, tamoxifen use for breast cancer and increased life expectancy (Reich 1992, Kitchener 2008). Given the anticipated increase in obesity, it is likely that this trend will continue.

Endometrial cancer has traditionally been believed to have a relatively good outcome. Whilst commonly believed to be a curable cancer in contrast to other gynaecological malignancies, the overall 5-year survival rate is disappointing considering that 75% of patients present with early (stage I) disease. Relative survival at both 1 and 5 years after diagnosis has risen steadily from 85% and 72%, respectively, in the late 1980s to 88% and 76% in the late 1990s (Cooper et al 2008). However, there is a significant gap in survival between the most affluent and the most deprived groups of approximately 4% based on data from England and Wales, with

survival lagging 2–6% behind Europe (Sant et al 2003, Cooper et al 2008). This deprivation gap may be best explained by comorbidities such as obesity, hypertension and cardiovascular disease, which are more common in deprived communities (Kitchener 2008). In addition, survival in advanced-stage endometrial cancer and poor prognostic types of endometrial cancer continues to be poor.

With the implementation of improving outcomes guidance in endometrial cancer, women with higher grade and poor prognostic types of endometrial cancer should be managed in gynaecological oncology centres, thus centralizing resources and experience, and facilitating trials that investigate new therapies for these patients (Department of Health 1999).

Epidemiology

Most studies focus on the epidemiology of endometrioid cancers, as the epidemiology for non-endometrioid histotypes is less clear (Box 42.1).

Obesity

Body mass index (BMI) plays an important role with a strong linear increase in risk with increasing BMI. There is a six-fold increase in women with a BMI greater than 40 kg/m² compared with those with a normal BMI (20–24 kg/m²), whereas women with a BMI under 20 kg/m² have half the risk (Lindemann et al 2008). The fact that obesity increases risk

Box 42.1 Factors known to alter the risk of developing endometrial cancer**Increase**

Obesity
 Diabetes mellitus
 High-fat/low complex carbohydrate diet
 Sedentary lifestyle
 Early menarche
 Late menopause
 Prolonged/irregular bleeding
 Nulliparity
 Polycystic ovary syndrome
 Functioning ovarian tumours
 Unopposed oestrogen therapy
 Personal history of breast or colon cancer
 Family history of breast, colon or endometrial cancer
 Tamoxifen use

Decrease

Late age at last birth
 Combined oral contraceptive
 Smoking
 Diet with high intake of fruit and vegetables
 Physical exercise

has been attributed to changes in concentrations of endogenous hormones in obese women. Oestrogens produced in adipose tissue have a direct mitogenic effect on endometrial cells. In postmenopausal women, oestrogens derived from peripheral adipose tissue are the primary source of endogenous oestrogen, and the rate of production is related to the size of the adipose depots. In younger premenopausal women, obesity can also be associated with anovulatory cycles, resulting in the absence of counterbalancing progesterone. Oligo- and amenorrhoeic women with polycystic ovary syndrome can develop endometrial hyperplasia and later carcinoma. There is a weight-related increase in insulin and insulin-like growth factor-I, both of which are endometrial growth factors. Cytokines produced in fat tissue (leptin and adiponectin) may play a direct role in endometrial carcinogenesis, as well as transcription factors that can modulate both cellular lipid metabolism and tumorigenesis. There is also a strongly increased risk of endometrial cancer in diabetics, possibly because of shared underlying mechanisms.

Tamoxifen

Tamoxifen improves the survival of postmenopausal women with hormone-receptor-positive breast cancer. Breast and endometrial cancer share several risk factors including age of menopause, unopposed oestrogen use and obesity, and breast cancer patients have an increased rate of endometrial cancer regardless of endocrine therapy. The risk of endometrial cancer rises with both the use of higher doses and increasing duration of tamoxifen use. Treatment beyond 5 years increases the risk at least four fold. However, the absolute risk of endometrial cancer is still very small in tamoxifen-treated women (Early Breast Cancer Trialists' Collaborative Group 1998). The use of aromatase inhibitors for postoperative adjuvant therapy instead of tamoxifen significantly reduces the risk of adverse gynaecological events (Duffy et al 2009). Switching from tamoxifen to an aromatase inhibitor may reduce the risk of endometrial cancer, but needs to be balanced against the side-effects and costs of therapy.

Box 42.2 Lifetime risk of malignancy in women with HNPCC

Colorectal	30–50%
Endometrial	40–60%
Ovarian	9–12%
Gastric	2–7%
Biliary	13–15%
Urinary	4–5%

Hereditary non-polyposis colorectal cancer

Hereditary non-polyposis colorectal cancer (HNPCC) is one of the most common cancer family syndromes. The estimated lifetime risk of developing endometrial cancer in women carrying these mutations is approximately 42–60%. HNPCC results from germline mutations in DNA mismatch repair genes and is autosomal dominant in inheritance (Froggatt et al 1996). As well as an increased risk of malignancies in the colon, cancers of the endometrium, ovary, biliary tract, stomach, small intestine and renal tract occur more commonly in these women (Box 42.2). Endometrial cancer is the most common and usually occurs in the premenopausal period. The majority of mismatch repair gene defects involve the genes *MSH2* and *MLH1*, with defects in *PMS1* and *PMS2* being less common (Papadopoulos and Lindblom 1997). A good family history will help to identify women who may carry these mutations. If such a mutation is found or if the woman is thought to be at high risk, there may be a role for prophylactic hysterectomy and bilateral salpingo-oophorectomy. Screening may be offered to those who do not wish to have surgery but with the caveat that there is no evidence that it is effective. There may also be a role for prophylactic progesterone in these women, and studies are currently investigating the role of the Mirena™ intrauterine system for prophylaxis.

Hormones

The combined oral contraceptive pill has a large protective effect that lasts for at least 20 years after cessation. Older hormone replacement therapy (HRT) regimens that utilized unopposed oestrogen in women with an intact uterus increase the relative risk of endometrial carcinoma approximately six fold after 5 years of use (Weiderpass et al 1999). It is strongly recommended that women with intact uteri should not be started on regimes containing oestrogen alone, and should be offered endometrial protection by regimes with either 10–12 days of cyclical progestogens or continuous combined regimens (Lethaby et al 2004).

Pathology

There is a growing consensus that endometrial cancers can be classified into two types based on clinical and molecular characteristics. Type I endometrial cancers (80%) are oestrogen dependent, usually arise in a background of endometrial hyperplasia, have well to moderately differentiated endometrioid histology, tend to be biologically indolent and have a good prognosis (Bokhman 1983). Type II cancers are not

oestrogen driven, have a higher grade, occur in a background of atrophic endometrium and have a poorer prognosis (Bokhman 1983). Uterine papillary serous carcinomas and clear cell carcinomas are considered to be type II endometrial cancers. These cancers, and uterine serous papillary cancer in particular, are characterized by early metastasis, resistance to therapy and a high mortality rate. Within the type II cancer histological subtypes, Creasman et al (2004) found 5-year survival of 81% for surgically staged stage I clear cell cancer and 72% for uterine papillary serous cancer. This is in comparison with over 95% for well to moderately differentiated stage IA endometrioid cancers. Although unusual cancers only account for 10% of endometrial cancers, they account for more than 50% of recurrences and deaths (Acharya et al 2005).

The morphological and clinical differences are paralleled by genetic distinctions (Hecht and Mutter 2006). Type I cancers are associated with mutations in the *K-ras2* oncogene, loss of the *PTEN* tumour suppressor gene, defects in DNA mismatch repair and near-diploid karyotype, whereas type II cancers are associated with mutations in *TP 53* and *ERBB-2* expression, and most are non-diploid. A dualistic model of endometrial tumorigenesis has been proposed which could explain the very different clinical outcomes in these groups of patients (Table 42.1, Figure 42.1). An understanding of the molecular heterogeneity of various histological types of endometrial cancer has the potential to lead to better individualization of treatment in the future (Maxwell et al 2005).

Malignancy may develop in either the glands or the stroma of the endometrium. Endometrial adenocarcinoma, derived from the endometrial glandular cells, is overwhelmingly the most common malignant tumour arising in the body of the uterus; the stroma is the origin of the much less common endometrial stromal sarcoma. Carcinosarcoma or malignant mixed Müllerian tumour comprises both glandular and stromal elements; however, carcinosarcomas are monoclonal and epithelial in origin, contrary to popular belief.

Histopathology

Endometrial carcinoma is usually seen as a raised, rough, perhaps papillary area occupying at least half of the endometrium. It often arises in the fundal region of the uterus; the internal os is rarely involved early in the disease (Figure 42.2). Myometrial invasion may be obvious to the naked eye. There seems to be no correlation between the degree of exophytic growth of the tumour within the uterine cavity and the presence of myometrial invasion.

There are several different histological subtypes of endometrial carcinoma (Table 42.2).

Microscopically, approximately 80% of malignant endometrial epithelial tumours are conventional adenocarcinomas which can be graded into well (grade 1, 50%), moderately (grade 2, 35%) and poorly differentiated (grade

Table 42.1 Clinicopathological characteristics and genetic abnormalities in type I and type II endometrial carcinomas

Characteristic	Type I	Type II
Unopposed oestrogen	Yes	No
Background endometrium	Hyperplastic	Atrophic
Morphology	Endometrioid	Serous, clear cell
Microsatellite instability	20–40%	0–5%
<i>p53</i> mutations	10–20%	90%

3, 15%). The International Confederation of Gynecology and Obstetrics (FIGO) grading takes into account the relative proportion of glandular and solid areas, as well as nuclear atypia. Approximately one-quarter of well-differentiated tumours have a papillary or villoglandular component. Such tumours need to be distinguished from serous papillary adenocarcinomas, which also show a papillary pattern but belong to the non-endometrioid, poorly differentiated type. Numerous morphological forms of endometrial adenocarcinomas exist, but while adenoacanthoma, adenosquamous carcinoma, secretory carcinoma and ciliated carcinoma are

Figure 42.3 A well-differentiated (grade 1) endometrial carcinoma of endometrioid pattern. Haematoxylin and eosin $\times 170$.

variants of ordinary endometrioid adenocarcinoma, papillary serous carcinoma, clear cell carcinoma and mucinous carcinoma are considered to be non-endometrioid.

Endometrioid adenocarcinoma

The most common endometrial carcinoma is referred to as endometrioid adenocarcinoma, the glandular pattern of which generally resembles that of normal proliferative-phase endometrium, although sometimes showing extreme complexity of the glands and cribriform pattern (Figure 42.3). Multilayering of the epithelial cells is nearly always seen. The secretory and ciliated cell variants are rare and well differentiated by definition. Secretory adenocarcinoma is a well-differentiated adenocarcinoma characterized by neoplastic glands with a subnuclear vacuolization resembling normal 17-day secretory endometrium. Mucinous adenocarcinoma is a low-grade neoplasm in which most of the cells contain prominent intracytoplasmic mucin, and should be distinguished from otherwise typical endometrioid carcinomas with abundant extracellular mucin but no intracellular mucin.

Endometrial adenocarcinoma with squamous metaplasia (adenoacanthoma)

Up to 25% of endometrioid-pattern endometrial adenocarcinomas contain areas of squamous metaplasia. Those tumours in which the squamous component is morphologically benign are commonly termed 'adenoacanthomas'. The squamous change is seen as islands of typical squamous epithelium, very often situated within the gland lumina or as surface or diffuse squamous metaplasia (Figure 42.4).

Adenosquamous carcinoma

Adenosquamous carcinoma is composed of malignant glands with a morphologically malignant squamous element. Histologically, the glandular element always predominates, making up at least 70% of the tumour. When matched by stage and grade, there are no prognostic differences between

Figure 42.4 Adenocarcinoma with benign squamous metaplasia (adenoacanthoma). Haematoxylin and eosin $\times 195$.

these variants. It is recommended that such tumours should be graded according to the grade of the glandular component. Squamous cell carcinoma is a rare primary tumour of the endometrium and can only be diagnosed as such in the absence of cervical involvement.

Papillary serous and clear cell adenocarcinomas

These are less common histological subtypes, both associated with a poor prognosis. Clear cell carcinoma is composed of large, clear cells containing glycogen, often forming papillary structures lined by 'hobnail' cells (Figure 42.5). Papillary serous carcinoma closely resembles ovarian papillary serous carcinoma, featuring severe atypia, a complex papillary pattern, high mitotic index, prominent myometrial invasion and psammoma bodies (Figure 42.6). Most patients are postmenopausal.

Mixed cancers

The conventional approach is to use a minimum 10% tumour volume of a specific histological type to warrant a specific diagnostic heading. Management should be guided by the worst component in histology.

Histopathological reporting

It is essential not only to recognize specific subtypes and to grade carcinomas accurately, but also to record the extent of myometrial invasion. The maximum depth of myometrial invasion, overall thickness of the myometrium, and minimum distance of the tumour from the serosal surface should be recorded. The presence of lymphovascular invasion should be noted. The cervical stroma, fallopian tubes and ovaries should all be examined carefully for tumour. Histopathological examination of the omentum would be valuable in uterine papillary serous carcinoma and clear cell carcinoma. The number of lymph nodes removed, the

Figure 42.5 Clear cell endometrial carcinoma with (A) acinar pattern and (B) papillary pattern.

number of lymph nodes positive for malignancy, extracapsular spread and the extent of lymphatic spread (e.g. node replaced with malignancy or not) should also be reported. There is no convincing evidence for routine ultrastaging or special immunohistochemical analysis of surgically removed lymph nodes (Figure 42.7).

The national minimum dataset published by the Royal College of Pathologists provides a useful tool for both gynaecologists and histopathologists. Serous carcinoma, clear cell carcinoma, and squamous and undifferentiated carcinoma are not graded, these tumours being highly malignant neoplasia. Sarcomas are also highly malignant neoplasms (Figures 42.8–42.11). The architectural grade, nuclear grade and FIGO grade of tumours can be used to separate patients

into groups with significantly different rates of progression of disease and relative survival.

Useful immunohistochemical markers

With improvements in immunohistochemistry, a panel of markers is frequently used by pathologists to improve the accuracy of histology and inform patient management.

Figure 42.11 Leiomyosarcoma. Although a few cells are spindled, most are poorly differentiated and show marked nuclear pleomorphism. Haematoxylin and eosin $\times 720$.

Immunohistochemistry for oestrogen receptors (ER) and progesterone receptors (PR) is performed to assess the sensitivity of tumours for hormonal therapy and to guide oncologists in the management of later relapse. Type I tumours tend to be ER and PR positive, *p53* negative and express low levels of the proliferation antigen Ki-67. Type II cancers tend to be ER and PR negative, *p53* positive with high Ki-67 labelling. Other markers can be performed to help in diagnosis. Wilms' tumour-1 (WT1) antibody staining is usually positive in uterine papillary serous cancers and can help distinguish from endometrioid adenocarcinomas with a papillary pattern of proliferation. In contrast to endometrial adenocarcinoma, endocervical adenocarcinoma is usually carcinoembryonic antigen positive, ER and PR negative and vimentin negative. *p16* is a marker for human papilloma virus and may be useful in distinguishing a cervical adenocarcinoma from endometrial adenocarcinoma with cervical extension.

Endometrial hyperplasia

Endometrioid endometrial cancers may be preceded by a preinvasive phase of background endometrial hyperplasia. However, the natural history and progression from endometrial hyperplasia to endometrial cancer is poorly understood, unlike preneoplasia of the cervix. Endometrial hyperplasia may be divided into simple, complex and atypical hyperplasia. In simple glandular hyperplasia, the endometrium is increased in volume and the glands show marked variations in shape, with many cystically dilated forms and pseudostratified lining epithelium that may show mitoses but lacks cytological atypia. In complex hyperplasia, there is more epithelial and glandular proliferation, with glandular budding and reduction in the stroma between glands. In atypical hyperplasia, epithelial cytological atypia is seen

which is defined as loss of nuclear polarization, enlarged rounded nuclei with hyperchromatism, chromatin clumping and enlarged nucleoli, and may be associated with a simple or a complex glandular pattern. Atypia is more often associated with complex than simple hyperplasia. Unfortunately, the diagnosis of atypical hyperplasia depends upon subjective criteria so there is substantial interobserver variability in the diagnosis. To date, no special techniques, such as ploidy, histochemistry or molecular biology, have demonstrated reproducible differences between atypical hyperplasia and well-differentiated adenocarcinoma.

Simple glandular hyperplasia is no longer considered to be a premalignant condition, but atypical hyperplasia is an ominous finding. Approximately 10–20% of all cases with atypia will have an underlying carcinoma present, and invasive cancer will develop later in up to 50% of cases. These figures are higher in the case of complex atypical hyperplasia than simple atypical hyperplasia (Silverberg 2000). Women with hyperplasia without cytological atypia may be treated with cyclical or continuous progestogens for 6 months and then undergo rebiopsy. Women with lesions showing cytological atypia who have finished childbearing should be offered a hysterectomy. The management of younger women with atypical hyperplasia is more difficult. Hyperplasia is discussed further in Chapter 38.

Spread of Disease

Endometrial carcinoma spreads by invading the myometrium. In some cases, it extends over the endometrial surface before penetrating the muscle layer. The more deeply it invades, the greater the likelihood of lymphatic or, less commonly, vascular involvement. Usually, initial lymphatic spread occurs to the external iliac, internal iliac and obturator group of lymph nodes. Further involvement of common iliac lymph nodes and para-aortic nodes can also occur. In approximately 5% of cases, para-aortic lymph nodes are involved without obvious histological involvement of the pelvic lymph nodes. Lymphatic spread may rarely include the supraclavicular or the inguinal nodes. Spread to the cervix may occur by extension along the surface (implants). This does not affect the prognosis, unlike infiltration of the cervical stroma. This is difficult to assess clinically (see below). Direct infiltration into the parametria is uncommon except when the cervix is involved.

In women with metastatic disease, spread to the ovaries is common. In 5% of cases (Gynecologic Oncology Group 2001), a synchronous primary ovarian cancer is noted. Transperitoneal spread occurs either when myometrial invasion reaches the serosal surface or via the fallopian tubes. This will involve the peritoneal surfaces and omentum in the same way as ovarian carcinoma. Clear cell and papillary serous carcinomas have a propensity to spread in this way, often without deep myometrial invasion.

The current FIGO staging criteria are shown in Box 42.3.

FIGO Staging

The FIGO surgical staging system is based on histopathological findings including myometrial invasion, and is important in determining prognosis and treatment post

hysterectomy. This staging system is based on findings in the uterus. As deep myometrial invasion or serosal involvement cannot always be visualized grossly, it is imperative that the pathologist samples the uterine corpus and cervix adequately for microscopic examination. Indicators of poor prognosis include high histological grade, deep myometrial invasion, unfavourable histological subtypes, lower uterine segment involvement by tumour, and myometrial vascular space invasion. The presence or absence of endometrial hyperplasia should be included in the report as aggressive carcinoma types are not associated with hyperplasia.

Depth of myometrial penetration is a more important guide to the likelihood of nodal metastases than tumour

grade (Table 42.3; Creasman et al 1987). Serous papillary and clear cell cancers have the highest risk of spread to para-aortic nodes. Only 10% of cases subsequently proven to have nodal spread had clinically enlarged nodes but, on the other hand, enlarged lymph nodes are not necessarily involved with metastatic disease. Serous papillary carcinoma of the endometrium, histologically similar to serous papillary cancer of the ovary, has a very poor prognosis and a pattern of spread akin to ovarian malignancy.

Positive peritoneal washings are present in approximately 12–15% of all cases of endometrial cancer, with half of these having no histological evidence of extrauterine spread. The Gynaecological Cancer Intergroup have proposed changes to the FIGO staging which have been incorporated into the revised FIGO staging for endometrial cancer (Box 42.3). They recommend that the grading of tumours is added to stage I tumours as this carries a direct clinical relevance. They also recommend removing the upgrading to stage IIIC on the basis of positive peritoneal washings, as these are very likely due to handling at the time of surgery and do not have independent prognostic significance; and that metastasis to positive inguinal lymph nodes is considered stage IIIC rather than stage IV. Although not part of FIGO staging, some centres perform a serum CA125 in women with endometrial cancer as reports suggest that an elevated serum CA125 at diagnosis indicates a high risk of subsequent recurrence but is less effective at predicting myometrial invasion than ultrasound.

Box 42.3 FIGO surgical staging of endometrial carcinoma

Stage I ^a	Tumor confined to the corpus uteri
IA ^a	No or less than half myometrial invasion
IB ^a	Invasion equal to or more than half of the myometrium
Stage II ^a	Tumor invades cervical stroma, but does not extend beyond the uterus ^b
Stage III ^a	Local and/or regional spread of the tumor
IIIA ^a	Tumor invades the serosa of the corpus uteri and/or adnexae ^c
IIIB ^a	Vaginal and/or parametrial involvement ^c
IIIC ^a	Metastases to pelvic and/or para-aortic lymph nodes ^c
IIIC1 ^a	Positive pelvic nodes
IIIC2 ^a	Positive para-aortic lymph nodes with or without positive pelvic lymph nodes
Stage IV ^a	Tumor invades bladder and/or bowel mucosa, and/or distant metastases
IVA ^a	Tumor invasion of bladder and/or bowel mucosa
IVB ^a	Distant metastases, including intra-abdominal metastases and/or inguinal lymph nodes

^aEither G1, G2, or G3.

^bEndocervical glandular involvement only should be considered as Stage I and no longer as Stage II.

^cPositive cytology has to be reported separately without changing the stage.

Modified from: Creasman W, Morrow C, Bundy B et al 1987 Surgical pathological spread patterns of endometrial cancer: a Gynecologic Oncology Group study. Cancer 60: 2035–2041.

sound scan performed for some other purpose. Endometrial cancer usually presents at an early stage as patients present with postmenopausal bleeding.

Postmenopausal bleeding

Postmenopausal bleeding is defined as an episode of bleeding 12 months or more after the last period. Postmenopausal bleeding is the most common presenting symptom, as 75–80% of women with the disease are in this age group. The most common mistake made that delays the diagnosis is to assume that vaginal spotting is due to atrophic vaginitis. Postmenopausal bleeding represents one of the most common reasons for referral to gynaecological services, largely due to suspicion of an underlying endometrial malignancy. Endometrial cancer is present in approximately 10% of patients referred with postmenopausal bleeding. No evidence has been identified to determine whether different patterns of postmenopausal bleeding, such as one-off or more frequent bleeds, are more or less likely to be associated with endometrial cancer.

Postmenopausal discharge

Diagnostic curettage in the patient with foul-smelling postmenopausal discharge due to a pyometra will reveal a carcinoma in approximately 50% of cases. It is usually in these women that the rare, pure squamous carcinoma is found.

Pelvic pain

The presence of pain usually indicates metastatic disease. It is often due to nerve compression on the pelvic side wall. Pyometra may present with a constant dull pain or cramping pain.

Symptoms in premenopausal women

Premenopausal women with endometrial carcinoma usually present with irregular bleeding, but over one-third complain of heavy but regular periods. All women over the age of 40 years who present with irregular menstrual bleeding persisting over 6 months should be investigated with an endometrial sample. Women at particular risk in the premenopausal age group include obese women with anovulatory cycles and women with polycystic ovary syndrome, and most gynaecological oncologists will remember anecdotal cases of endometrial cancer in the under 40s diagnosed during investigations for infertility. Consideration should be given to performing a pipelle sample in women under 40 years of age with irregular menstrual bleeding who are in high-risk groups (e.g. obese women with infertility, women with polycystic ovary syndrome).

Clinical examination

Physical examination will seldom suggest the diagnosis of endometrial carcinoma, but several signs should be sought in women with postmenopausal or perimenopausal bleeding.

- Enlarged lymph nodes in the groin or supraclavicular fossa.

- A metastatic focus in the vagina may lie behind the blades of the speculum, commonly on the anterior wall.
- The uterus may be enlarged, an unusual finding in a postmenopausal woman, or spread to the adnexae or parametrium may be felt.
- The breasts should be palpated because breast cancer can sometimes present with the symptoms caused by uterine or ovarian spread (Scottish Intercollegiate Guidelines Network 2002).

Investigations and Diagnosis of Endometrial Cancer

Patients with suspicious symptoms should initially be investigated with a transvaginal ultrasound to investigate the endometrial cavity. Transvaginal ultrasound is useful in the investigation of women with postmenopausal bleeding because it helps to identify those at higher risk of endometrial cancer who require further investigation, and is also an effective means of excluding endometrial cancer. Transvaginal ultrasound measurement of endometrial thickness of less than 5 mm can be a good diagnostic index (Scottish Intercollegiate Guidelines Network 2002). The pooled sensitivity and specificity of endovaginal ultrasound in the detection of endometrial cancer if a cut-off of 5 mm was used were 96% [95% confidence interval (CI) 94–98%] and 61% (95% CI 59–63%), respectively. Sensitivity decreased and specificity increased with increasing thresholds. Thin (<5 mm) endometrial measurement on endovaginal ultrasound can exclude endometrial disease in the majority of postmenopausal women with vaginal bleeding, regardless of hormone replacement use (Smith-Bindman et al 1998).

The mean endometrial thickness in women on sequential HRT with postmenopausal bleeding is greater than that in women with postmenopausal bleeding who are not on sequential HRT. Thus, an abnormal endometrial thickness in women with postmenopausal bleeding who are not using sequential HRT represents a greater probability of endometrial disease than in women taking HRT (Gupta et al 2002). Women presenting with postmenopausal bleeding and taking tamoxifen have a higher probability of malignancy (substantially >10%). In these cases, the ultrasound image is more difficult to interpret. Therefore, it is advisable to sample the endometrium initially and examine the cavity hysteroscopically.

Endometrial biopsy

A definitive diagnosis in postmenopausal bleeding is made by histology. The diagnosis of endometrial cancer is made by an endometrial sample obtained either in the outpatient setting by a pipelle endometrial sample, or through outpatient hysteroscopy which allows the operator the advantage of targeted biopsy and removing small polyps if necessary. Hysteroscopy under anaesthetic should be reserved for selected cases where the os does not admit an endometrial sampling device despite lithotomy, gentle volsellum traction on the cervix and adequate illumination.

Historically, endometrial samples have been obtained by dilatation and curettage (D&C). This involves curetting the walls of the uterine cavity in a systematic fashion. The

significant drawback of D&C is that it is a 'blind' procedure and the uterine cavity is not likely to be sampled adequately. Hysteroscopy offers the advantage of a visually targeted biopsy, particularly in focal lesions on a background of atrophic endometrium. Endometrial samplers work on the principle that cancer cells are more likely to detach from the endometrium and be aspirated by suction exerted by the device. These plastic-tube-like devices are inserted into the uterine cavity and a plunger is withdrawn, resulting in 'negative' pressure which permits aspiration of tissue into the device. In a small proportion of patients, outpatient endometrial sampling is not technically possible. Outpatient endometrial sampling has a procedure failure rate as well as a tissue-yield failure rate, each of approximately 10%. It should be noted that yield failures are not unexpected in women with atrophic endometrium, whereas failure to obtain tissue would be less likely if cancer was present.

Hysteroscopy

Hysteroscopy allows the operator to visualize the endometrial cavity. The procedure can be performed either in an outpatient setting with the patient awake or under general anaesthesia. A biopsy of the endometrium is usually taken following hysteroscopy, either with a sampler or by curettage. Hysteroscopy in the outpatient setting appears to have an accuracy and patient acceptability equivalent to inpatient hysteroscopy under general anaesthetic. Facilities to perform hysteroscopy and curettage under general anaesthetic should be available for occasions when the outpatient procedure is not possible or the patient has a strong preference for a general anaesthetic.

One-stop postmenopausal bleeding clinic

The current standard of care in the UK is to establish a one-stop rapid access clinic with facilities for transvaginal ultrasound and endometrial biopsy with or without hysteroscopic evaluation of the uterus to investigate these women. Following such assessment, reassurance can be given or further investigations undertaken.

Investigation of women using tamoxifen

Women with breast cancer who take tamoxifen on a long-term basis are at increased risk of endometrial cancer. In view of the increased risk of endometrial cancer associated with tamoxifen therapy, there is a case for heightened vigilance for postmenopausal bleeding by both the women and the clinician(s) responsible for their care. Current evidence does not justify the use of any investigation (ultrasonography, hysteroscopy, endometrial biopsy or D&C) in postmenopausal women receiving treatment with tamoxifen in the absence of vaginal bleeding. Ultrasonography is poor at differentiating potential cancers from other tamoxifen-induced thickening because of the distorted endometrial architecture associated with long-term use of tamoxifen. Furthermore, endometrial thickness is not a useful discriminator in this group. Hysteroscopy with biopsy is preferable as the first line of investigation in women taking tamoxifen who experience postmenopausal bleeding.

Recurrent postmenopausal bleeding

There is no evidence to recommend when reinvestigation should take place following recurrent or persistent postmenopausal bleeding. Clinical judgement is required, but consideration of reinvestigation must be given if postmenopausal bleeding persists after 6 months in view of the false-negative rate associated with all methods of diagnosis. 'Beware the weeping womb' is an old but useful aphorism.

Screening for Endometrial Cancer

As most patients with endometrial carcinomas present early, it is unlikely, based on current technology, that a population screening programme would be of any value. Routine screening in asymptomatic women for endometrial carcinomas is currently not justified. Women at risk, including those on tamoxifen and families with hereditary non-polyposis colon cancer, have a higher risk of endometrial cancer and should report any bleeding or spotting. Ultrasound screening is not recommended for women on tamoxifen. Whilst a Pap smear is not a screening test for endometrial cancer, the incidental finding of endometrial cells on a Pap smear in a postmenopausal woman requires investigation.

Preoperative Evaluation

A transvaginal ultrasound report should also include an assessment of ovarian morphology as synchronous primary ovarian cancers, oestrogen-producing tumours or endometrial cancer metastasis can be identified in this way. Some centres also perform magnetic resonance imaging (MRI) in order to plan management such as reserving pelvic lymphadenectomy for deeply invasive lesions. Computed tomography (CT) scan of the abdomen and pelvis in uterine papillary serous cancer is advisable to detect upper abdominal disease. A CT of the chest is advisable in women with carcinosarcoma to exclude pulmonary metastasis. If the diagnosis of endometrial carcinoma is confirmed, a chest X-ray is essential. A full blood count, urea, creatinine and electrolyte estimations are required, as is urinalysis for sugar and protein.

If preoperative radiological assessment is undertaken, it seems that MRI is the most accurate for assessing local spread to the cervix and through the myometrium. Neither CT nor MRI is sufficiently sensitive to detect small, involved lymph nodes. Many patients also require medical optimization as these patients are frequently elderly with multiple comorbidities. Assessment by an anaesthetist may be helpful in determining fitness for surgery.

Treatment

Surgery for early-stage endometrial cancer

The mainstay of treatment in stage I endometrial cancer is a total abdominal hysterectomy and bilateral salpingo-oophorectomy, with pelvic and para-aortic lymphadenectomy in selected cases. Both transverse incisions and midline incisions can be utilized; however, a midline umbilical incision allows the best access to the abdominal cavity since it

can be extended easily to above the umbilicus if para-aortic nodes are thought to be involved or if unsuspected upper abdominal metastases are detected. In the very obese patient with an 'apron', it is best not to straighten out the abdominal wall by pulling up the panniculus of fat over the pubic symphysis. Retraction of this fat is often tiresome, exposure can be suboptimal and the incidence of wound infection in the skinfold is high. 'Panniculectomy' with removal of skin and fat to the fascia using a wide transverse elliptical incision does give good access to the pelvic side walls, although it adds to the duration of the procedure. The other option, favoured at the authors' centre, is to perform a midline incision extended above the umbilicus if necessary to avoid the infraumbilical apron of fat.

Once the abdominal cavity is entered, washings should be taken from around the uterus, bladder and pouch of Douglas, and a full laparotomy performed with particular attention being paid to the liver, omentum, uterine adnexal and retroperitoneal node-bearing areas. A simple extrafascial total abdominal hysterectomy and bilateral salpingo-oophorectomy is undertaken. There is no need to remove a vaginal cuff. A complete pelvic lymphadenectomy involving common iliac nodes, external iliac nodes, internal iliac nodes and obturator nodes down to the level of the obturator nerve may then be performed in selected patients with a higher risk of lymph node metastasis (see below).

In patients with high-risk histology features on preoperative biopsy, particularly uterine papillary serous cancer, the upper abdomen, omentum and liver should be assessed as these cancers metastasize to the upper abdomen like ovarian cancer. Surgery for carcinosarcoma can be challenging as the uterus is frequently fixed and pelvic spread is common. Removal of a large piece of infracolic omentum is recommended in women with uterine papillary serous cancer and clear cell cancer, since microscopic disease in the omentum may be present. In approximately 5% of cases, positive para-aortic nodes can be identified in the absence of involved pelvic lymph nodes. The incidence of nodal positivity is summarized in Table 42.3.

Role of lymphadenectomy

Two large independent surgical randomized controlled trials found that routine pelvic and/or para-aortic lymphadenectomy confer no therapeutic benefit. The Italian randomized controlled trial and the Medical Research Council's ASTEC (A Study in the Treatment of Endometrial Cancer) trial differed in the extent of lymphadenectomy and use of postoperative radiotherapy (Benedetti Panici et al 2008, Kitchener et al 2009). However, lymphadenectomy may still play a role in accurate surgical staging and tailoring of adjuvant therapy. In the authors' institution, regional lymphadenectomy is performed for patients estimated to have a risk of nodal metastasis greater than 10%; this includes stage IC, grade 3, unusual histology subtypes of patients. A pelvic lymphadenectomy is performed in patients with a preoperative biopsy showing grade 2–3 endometrial cancer and myometrial invasion greater than 50% on MRI (presumed stage IC, grade 2–3). Para-aortic lymphadenectomy is reserved for clinically enlarged lymph nodes at MRI or laparotomy. However, practice differs among centres in the UK and elsewhere regarding the extent of lymphadenectomy.

This protocol is based on balancing the risks of adjuvant radiotherapy and the knowledge of lymph node involvement conferred by surgical staging. Omitting pelvic radiotherapy in adequately staged patients with a stage IC, grade 3 tumour spares the not-inconsiderable risks of external beam radiotherapy to the pelvis in approximately two-thirds of patients. Pelvic lymphadenectomy should only be performed in the context of a trial unless it is used to guide adjuvant management. Sentinel nodes to identify the draining lymph node in endometrial cancer have been investigated, but at present this is solely a research technique. The role of positron emission tomography (PET) scanning to estimate nodal status in this group of patients has not been established in prospective trials.

Laparoscopic surgery for endometrial cancer

Laparoscopic surgery for primary management of endometrial cancer has been successfully reported, with several case series reporting satisfactory outcomes for both survival and morbidity (O'Hanlan et al 2004, 2005, Ghezzi et al 2006, Barakat et al 2007, Istre et al 2007). A meta-analysis of laparoscopic surgery for endometrial cancer establishing its feasibility and efficacy has been published (Lin et al 2008). Three techniques exist: laparoscopically assisted vaginal hysterectomy and laparoscopic hysterectomy where the uterine arteries are divided laparoscopically; and total laparoscopic hysterectomy (TLH) where the entire procedure is completed laparoscopically. In TLH for endometrial cancer, the entire hysterectomy procedure is performed laparoscopically, including division of the uterine vessels, the uterus is removed through the open vault of the vagina and the vagina is sutured laparoscopically. TLH may have technical advantages in the obese nulliparous population where vaginal access may be difficult and there is no vaginal descent (O'Hanlan et al 2004, Ramirez et al 2006).

A large randomized trial of laparoscopy vs laparotomy for surgical staging of endometrial cancer has been published in abstract form by the Gynecologic Oncology Group (GOG) (Walker et al 2006). The trial established the efficacy of laparoscopic surgical staging, with 74.2% of patients randomized to receive laparoscopy undergoing successful staging. Other benefits favouring the laparoscopic arm were improvement in quality of life, decreased hospital stay and fewer complications greater than grade 2. Survival results are pending at this time. However, the survival and morbidity associated with TLH compared with conventional open surgery have not been established in a randomized clinical trial, and this is being addressed in LACE (Janda et al 2006).

The majority of endometrial cancers in the UK have been managed through laparotomy; in a recent randomized controlled trial of lymphadenectomy and external beam radiotherapy in endometrial cancer (ASTEC), less than 10% of hysterectomies in the UK were performed using minimal access techniques. However, laparoscopic expertise amongst gynaecological oncologists is increasing, and more surgeons are now offering laparoscopic surgery for women with endometrial cancer. In the authors' centre, all patients with endometrial cancer are considered for laparoscopic surgery. Exclusion criteria are uterine size greater than 10–12 weeks, multiple previous laparotomies and anaesthetic factors preventing steep Trendelenberg position.

Surgery for advanced-stage endometrial cancer

In patients with clinically suspected stage II endometrial cancer with cervical involvement, a radical hysterectomy to achieve tumour clearance may be performed. Occasionally, at laparotomy for stage I disease, particularly for poor prognostic histotypes, macroscopic spread to the omentum and pelvic/para-aortic lymph nodes is identified. It is reasonable to attempt a macroscopic clearance of all deposits in an attempt to 'debulk', akin to ovarian cancer prior to adjuvant chemotherapy, as this may improve outcome. Most patients with advanced-stage endometrial cancer may be best managed by total abdominal hysterectomy and bilateral salpingo-oophorectomy with primary palliative intent to prevent troublesome vaginal bleeding. Carcinosarcomas in particular deeply infiltrate the pelvis and may prove inoperable. A hysterectomy may also be performed in stage IV disease with distant metastasis as effective palliation to reduce bleeding.

Non-surgical management of endometrial carcinoma

Non-surgical management of endometrial carcinoma involves radiotherapy, chemotherapy and hormonal therapy.

Radiotherapy

After surgery, radiotherapy is the most common modality of treatment used in endometrial cancer. It has a role in most stages of this disease. The use of radiotherapy began empirically, but, more recently, randomized trials have confirmed its benefits. The most important role is as adjuvant therapy following surgery in early-stage disease, but it also provides good palliation in advanced-stage disease. In circumstances where surgery may be very high risk, definitive treatment

with radiotherapy alone can be considered. The following discussions will present evidence for adjuvant radiotherapy as per the old FIGO staging for endometrial cancer.

Stages IA and IB, grades 1 and 2

For the usual histological type of endometrioid adenocarcinoma which is well differentiated (grade 1) or moderately differentiated (grade 2), there is usually no indication for any adjuvant treatments. This is because the risk of local recurrence is very low (0–9%) (GOG 33) and radiotherapy is unlikely to be of significant benefit, especially when the majority of recurrences are salvageable by further treatment.

Stages IA and IB, grade 3 or high-risk histology

Poorly differentiated endometrioid adenocarcinoma, clear cell carcinoma and papillary serous carcinoma pose a higher risk of not only locoregional but also systemic recurrence. This is evident from their poorer relapse-free survival (RFS) and overall survival (OS) compared with grades 2 and 3 endometrioid adenocarcinomas (Creasman et al 2004). Five-year survival rates for papillary serous carcinoma, grade 3 endometrioid carcinoma and clear cell carcinoma are 72%, 76% and 80%, respectively. Almost half of those perceived to have early-stage uterine papillary serous carcinoma are found to have advanced-stage disease at surgery or in the definitive pathology. OS and progression-free survival (PFS) slip down to 80% and 68%, respectively, for stage I uterine papillary serous carcinoma. Recurrence rates were as high as 29% for stage IB–IC uterine papillary serous carcinoma (Havrilesky et al 2007a). While systemic management of this particular category is still evolving, radiotherapy has been in use for decades to at least reduce the risk of locoregional recurrence. Historically, this has been achieved mainly by external beam radiotherapy as this would encompass most pelvic lymph nodes including obturator, internal iliac, external iliac and common iliac, which are the main lymph node

Table 42.4 Trials of adjuvant radiotherapy in endometrial cancer

Publication year	Trial	No. of patients	Inclusion criteria	Outcome
2000	PORTEC 1*	715	Stage IA, grade 3; stage IB, any grade; or stage IC, grade 1–2	Local recurrence 13.7% vs 4.2%
2004	Gynecologic Oncology Group 99†	392	Stages IB–C or IIA–B	Local recurrence 26% vs 6%
2001‡	Fanning‡	66/265	Stage IC, grade 3; or stage IIA–B	5-year overall survival 84%, disease-free survival 97%
2008§	PORTEC 2	427	Age >60 years: stage IC, grade 2–3; or stage IB, grade 3. Any age: stage IIA, grade 1–2	3-year pelvic nodal recurrence rate 3.5% vs 0.6%
2009¶	ASTEC	789	Stage IA–B, grade 3; stage IC, any grade; stage IIA; or serous papillary	NA

groups to which endometrial cancer would metastasize (Table 42.4).

In the largest postoperative radiotherapy trial in endometrial cancer (PORTEC 1), 715 patients with FIGO stage IC, grades 2 and 3, stage IB, any grade and stage IA, grade 3 endometrioid carcinoma, serous papillary carcinoma and clear cell carcinoma were randomized to receive either external beam radiotherapy or no adjuvant radiotherapy following total abdominal hysterectomy, bilateral salpingo-oophorectomy and washings (Creutzberg et al 2000). Adjuvant radiotherapy reduced the risk of locoregional recurrence from 13.7% to 4.2%, which was statistically significant. The distant metastasis rate (7.9% vs 7%, respectively) and death due to distant metastases (6.4% vs 4.5%, respectively) at 5 years were similar in the radiotherapy and observation arms. There was no significant difference in survival between the treated and non-treated groups. Higher age of the patient (≥ 60 vs < 60 , hazard ratio 3.1, $P = 0.02$) and poor differentiation of the tumour (grade 3 vs grade 2, hazard ratio 4.9, $P = 0.0008$) were significant risk factors for cancer-related deaths. The risk of gastrointestinal toxicity was increased from 1% to 17% ($P = 0.0001$) in the treated group. PORTEC 1 registered 99 patients with FIGO stage IC, grade 3 endometrial carcinoma for analysis purposes only as they all received radiotherapy (Creutzberg et al 2004). Five-year distant metastasis rate was higher for FIGO stage IC, grade 3 compared with FIGO stage IC, grade 2 endometrial carcinoma (31% vs 20%, respectively) in patients treated with adjuvant radiotherapy. Five-year survival was 74% vs 58% for stages IB and IC, respectively.

Another study by the GOG looked at the value of adjuvant radiotherapy following definitive surgery that involved selective pelvic lymph node dissection (Keys et al 2004). Three hundred and ninety-two patients with intermediate risk of recurrence (FIGO stages IB, IC, IIA and IIB) who underwent total abdominal hysterectomy, bilateral salpingo-oophorectomy, selective pelvic lymphadenectomy and selective para-aortic lymph node dissection were randomized to either adjuvant radiotherapy to the pelvis or no further adjuvant treatment. Based on GOG 33 trial, three factors were considered as risk factors: grade 2–3, involvement of outer third of myometrium and lymphovascular space invasion. Patients were considered to be at high–intermediate risk of recurrence if they were aged 70 years or more with one risk factor, 50 years or more with two risk factors, or any age with all three risk factors. It is interesting to note that one-third of stage I patients meet this criteria and that two-thirds of recurrences occur in this group. Risk of recurrence in patients at high–intermediate risk was reduced to 6% with radiotherapy compared with 26% when no adjuvant radiotherapy was given. At 4 years, there was a trend towards better survival with radiotherapy (92% vs 86%), although this was not statistically significant. The trial, however, was not powered to detect a survival advantage.

Two trials have evaluated the usefulness of brachytherapy without external beam radiotherapy, also labelled as ‘teletherapy’. The first of these studies was a prospective non-randomized study (Fanning 2001). Two hundred and sixty-five patients underwent complete surgical staging with full lymphadenectomy up to the duodenum, undertaken by one surgeon. Sixty-six patients were identified to have intermediate-risk disease on the basis of grade 3, involve-

ment of outer myometrium (FIGO stage IC) or involvement of cervix (FIGO stage IIA–B), and all received adjuvant brachytherapy but no external beam radiotherapy. Five-year survival was reported to be 84% and PFS was 97%. Although one should avoid comparing the results of two different trials, it was noted with interest that this PFS was comparable with the PFS observed in GOG 99 trial for a similar group of patients who received teletherapy. The second pivotal randomized trial of adjuvant brachytherapy compared with external beam radiotherapy was planned on the basis of similar observations in phase II trials (PORTEC 2). Patients at high–intermediate risk (on the basis of PORTEC 1 results) were randomized to receive either external beam radiotherapy or brachytherapy. The primary endpoint was vaginal recurrence rate, and secondary endpoints were quality of life, OS and locoregional recurrence. The analysis was by intention to treat. A total of 427 patients were randomized into the two treatment groups. Three-year vaginal recurrence rate was 1.9% ($P = 0.97$ in both groups). Three-year pelvic nodal recurrence rate was 0.6% in the external beam radiotherapy group compared with 3.5% in the brachytherapy alone arm ($P = 0.03$). Three-year OS and RFS rates were 90.4% and 90.8% ($P = 0.55$) and 89.5 and 89.1 ($P = 0.38$), respectively. The distant recurrence rates were similar in both groups.

ASTEC is a large phase III, randomized trial which addressed two issues, namely the role of lymphadenectomy and adjuvant radiotherapy in early-stage endometrial cancer (Kitchener et al 2009). Although the results of the lymphadenectomy part of the trial have recently been published, the results of the radiotherapy part are not yet in the public domain.

Usually, a dose between 40 and 50 grays (Gy) is given in 20–28 fractions over 4–5.5 weeks using megavoltage (MV) photons of higher energy (typically between 8 and 15 MV). The side-effects of radiotherapy are described as early (usually temporary and appearing during treatment and up to 3 months after) or late (usually permanent and typically occurring more than 3 months after radiation therapy). Early side-effects include tiredness, diarrhoea, local soreness of skin/vagina, local hair loss and radiation cystitis. Delayed toxicity includes the risk of chronic proctitis or a weak bladder leading to poor control, urinary urgency and occasionally incontinence, but most importantly the risk of a fistula (involving bowel, vagina or urinary bladder) or narrowing of the bowel which may require colostomy. Obviously, this risk is directly proportional to the dose of radiotherapy and the amount of bowel in the radiation field. The risk is less than 5% over 5 years at the doses mentioned above (Milano et al 2007). Comorbidity, especially previous pelvic operations and inflammatory bowel disease, increase this risk significantly and therefore are relative contraindications to radiotherapy to the pelvis. Similarly, hereditary conditions including ataxia telangiectasia and xeroderma pigmentosum markedly increase radiation sensitivity, and are absolute contraindications to adjuvant radiotherapy.

Stages IC, IIA and IIB

Involvement of the outer half of the myometrium and cervical stroma are well known to increase the risk of local recurrence as well as regional lymph node spread. As many as one-third of patients with apparent stage IC, grade 2 tumours may have pelvic nodes involved, and one-quarter may have

para-aortic nodes involved. There has been a definite role for radiotherapy in these stages following surgery to reduce that risk. The modality of radiotherapy, the dose and the extent of the area radiated have not been without controversy. While preliminary results of the largest phase III randomized trial of adjuvant radiotherapy in the UK do not show any advantage for external beam radiotherapy for stage IC disease, the fact that some centres were allowed to use brachytherapy in accordance with their local guidelines has made interpretation difficult. In fact, most radiation/clinical oncologists continue to offer radiotherapy to this group of patients, and were reluctant to recruit these patients into any trials of adjuvant radiotherapy or not. For these reasons, the PORTEC 1 trial excluded stage IC, grade 3 patients from randomization although they were registered in the trial to follow their progress (Creutzberg et al 2004).

With the adoption of pelvic lymphadenectomy, the use of external beam radiotherapy in early-stage cancer is being replaced by localized brachytherapy, eliminating the need for radiating a large pelvic volume including pelvic nodes. While the issue of pelvic node surgery in early endometrial cancer has been controversial and open to debate, patients who do undergo this type of surgery and who are node negative may be eligible for brachytherapy alone. The PORTEC 2 trial has shown no differences in vaginal vault recurrence rates between patients who had external beam radiotherapy or brachytherapy. However, the recent ASTEC publication discouraged the routine use of pelvic lymphadenectomy outside of a clinical trial (Kitchener et al 2009). This is unfortunate as it would lead to inadequate staging of endometrial cancer patients and hence deny adjuvant treatments to those with higher stage disease. Obviously, there are also significant implications of this in terms of acute and long-term toxicity of radiotherapy. There is a definite need for more evidence to finally resolve this issue. Detailed discussion on this subject is outwith the scope of this chapter.

If the cervix is involved, external beam radiotherapy is usually followed by brachytherapy. Brachytherapy is administered by a remote afterloading system. The intention is to boost the vaginal vault with a higher dose of radiotherapy without giving an excessive dose to the small bowel. In brachytherapy, sources of radiation are placed near the area of interest so that the area nearest to the source receives a higher dose, and the normal tissues (organs at risk) away from the source receive a much smaller dose, thereby reducing the risk of serious morbidity.

Stages IIIA, IIIB and IIIC

Locally advanced endometrial cancer has a lower OS rate but there is also a significant risk of local recurrence. While the prognosis is usually determined by distant recurrence, local relapse can be distressing and uncomfortable, with intractable symptoms such as pain, bleeding, discharge, and fistulation into the vagina, bladder and rectum. Involvement of ureters or bladder usually leads to renal impairment, compromising further cytotoxic therapy. If patients are suitable for chemotherapy, they usually receive this first, followed by radiotherapy.

Stage IVA

An attempt should be made to deliver a radical dose of radiotherapy in otherwise fit patients. This may include

external beam radiotherapy as well as brachytherapy. The aim in the first place is to control the local disease, and hence the local symptoms, but a small number of patients may be salvaged. They may go on to live for many years (Churn and Jones 1999). For the majority, a palliative dose of radiation is given to help local symptoms.

Stage IVB

The aim of radiotherapy is almost always palliation in this situation. Virtually any part of the body can receive a palliative dose, but, for obvious reasons, the most common site to be treated is the pelvis. Either external beam radiotherapy or brachytherapy can be used. This aims to help symptoms such as pain, bleeding and spinal cord compression, but also those that arise from the mass effect of raised intracranial pressure from brain metastases. The total dose and number of fractions depend on the site, extent, tempo of the disease and fitness of the patient. Most commonly used doses are 8 Gy in a single fraction, 20 Gy in five fractions over 1 week, and 30 Gy in 10 fractions over 2 weeks.

Radiotherapy technique

The quality of planning and delivery of radiotherapy has improved remarkably over the last few years in line with the improvements in computer and technological advances (Figure 42.12). The latest state-of-the-art multi-leaf-collimator-equipped linear accelerators with ability to deliver gated, conformal MV radiotherapy are in stark contrast with the old orthovoltage (KV) machines with limited planning techniques. For external beam radiotherapy, the patient first undergoes a planning scan which is usually a CT scan, although MR scans are likely to replace CT for this purpose. Work is also ongoing to explore the usefulness of PET-CT and PET-MRI in radiotherapy planning (Figure 42.13). After the planning CT, patients are marked with tattoos (usually pin head size) to ensure reproducibility of the treatment position during each fraction of radiotherapy. Clinical or radiation oncologists then draw the target volume, i.e. the area to be treated (Figures 42.14 and 42.15). Most patients are treated using a four-field plan (brick technique) to reduce the dose of radiation to normal tissues around the target volume (Figures 42.16 and 42.17). Once the physicist

has planned the treatment and it is approved by the oncologist, treatment can be started. There are many quality assurance and safety nets at different stages to ensure safe radiation exposure in line with the local radiation protection laws. One treatment is given per day, Monday to Friday, with no treatment over the weekend. Patients can be treated over the weekend or even twice a day depending upon the availability of resources and staff. If treated twice a day, there has to be a minimum gap of 6 h between treatments to allow the normal tissue repair to take place. Patients are reviewed weekly to assess for any side-effects.

Where needed, brachytherapy is delivered using afterloading devices. In recent years, there has been a gradual move from low- (LDR) to medium-dose-rate (MDR) brachytherapy (dose rates <1200 cGy/min) and now to high-dose-rate (HDR) brachytherapy (dose rates >1200 cGy/min), meaning

that the treatment can now be given in a few minutes rather than many hours. The results of HDR brachytherapy in cervical cancer confirm its efficacy at no significant additional toxicity (Lertsanguansinchai et al 2004). LDR and MDR brachytherapy require a single insertion, while HDR brachytherapy requires two to four treatments depending on the dose needed. Also, the total dose required is less for HDR systems.

Depending upon the dose required and the aim of treatment, one to three applicators are placed vaginally to treat the uterus, vaginal vault or both. This is usually done under general or spinal anaesthetic, but can be carried out under local or even no anaesthetic, especially in postoperative cases where only vault radiation is required. Patients are treated in isolation rooms for radiation protection. The applicators are connected to the tubes from the radiation delivery

machine holding radiation sources. Once all planning is complete and rechecked and all staff have left the room, the machine can be switched on. Patients should be able to lie on their backs and keep their legs straight for many hours for LDR and MDR brachytherapy, although they can be treated while under anaesthetic for HDR brachytherapy.

Radiotherapy for recurrent disease

Proponents of radiotherapy claim that many of the recurrences are not localized, while advocates of no adjuvant radiotherapy for early disease stress that the majority of recurrences (although not all) are localized and therefore are salvageable, the so-called 'Alabama approach' (Barnes and Kilgore 2000). This approach, although not widely popular, is being adopted by some in view of no survival advantage of adjuvant radiotherapy and a definite, although small, risk of late serious toxicity of radiotherapy. Recurrent, localized disease at the vault can be treated with radiotherapy or surgery, and success rates are high (Creutzberg et al 2003).

If radiotherapy is used, the doses required are high and the risk of toxicity is proportionally high. Nevertheless, any patient with localized recurrence should be viewed as potentially curable.

Chemotherapy

The role of chemotherapy is less well established. There are many reasons for this, but mainly the comorbidities of typical endometrial cancer patients such as hypertension, diabetes mellitus, obesity and related problems, combined with the myth that early endometrial cancer has excellent survival, have discouraged oncologists from exploring this avenue in the past. However, improvements in general health care, refinements of cytotoxic agents, the use of granulocyte colony-stimulating factor and 24-h medical/nursing support for such patients has resulted in a refreshed interest in assessing the role of chemotherapy.

Early-stage localized disease has excellent survival after surgery and it would be difficult to demonstrate any benefit from adjuvant chemotherapy. In high-risk early-stage disease, the risk of systemic relapse is high and so is the 5-year disease-specific mortality rate. Papillary serous carcinoma, clear cell carcinoma and poorly differentiated endometrioid carcinoma infiltrating the outer half of the myometrium are particularly associated with poor OS (5-year OS 70–80%) (Murphy et al 2003). These high-risk scenarios may benefit from adjuvant chemotherapy. Until recently, there were no convincing phase III data to show a survival benefit for the use of chemotherapy; based on retrospective data, many oncologists were considering fitter patients for adjuvant chemotherapy, especially if they had serous carcinoma or even elements of clear cell carcinoma. Evidence is now gradually accumulating to support this approach. Most oncologists now agree that serous papillary carcinoma should be treated as ovarian carcinoma with adjuvant chemotherapy. A recently published systematic review (Table 42.5) evaluated data collected from 2288 patients recruited into 11 trials of chemotherapy for advanced disease.

A GOG study showed better OS of 15.3 vs 12.3 months, PFS of 8.3 vs 5.3 months and overall response rate of 57 vs 34% in favour of the addition of paclitaxel to the combination of doxorubicin and cisplatin, but at the cost of much higher toxicity (Fleming et al 2004). Combinations of an anthracycline and platinum are still probably the most commonly used regimes in endometrial carcinoma.

The Japanese GOG study showed that early-stage high-risk patients, including stages IC, grade 3, II and IIIA, had higher PFS (83.8% vs 66.2%, $P = 0.024$) and OS (89.7% vs 73.6%, $P = 0.006$) when treated with combination chemotherapy comprising cyclophosphamide, adriamycin and cisplatin compared with treatment with pelvic radiotherapy alone (Susumu et al 2008). A phase II feasibility study by the Radiation Therapy Oncology Group used concurrent chemotherapy (cisplatin 50 mg/m² on days 1 and 28) during external beam radiotherapy of 45 Gy in 25 fractions followed by four cycles of adjuvant combination chemotherapy with cisplatin 50 mg/m² and paclitaxel 175 mg/m² four weekly (Greven et al 2006). Forty-six patients with grade 2 or 3 endometrial adenocarcinoma with FIGO stages between IC, IIB and IIIB were treated and followed-up to a median of 4.3

Table 42.5 Systematic reviews of chemotherapy in advanced endometrial carcinoma

Year	Author	Size	Study arm	Control arm	Median PFS (months)	ORR (%)	Overall survival (months)
1978	Horton	40	Dox	Cyclo	NA	19 vs 0	NA
1984	Cohen	155	Dox, 5-FU, cyclo, mega	Mel, 5-FU, mega	6.1 vs 5.2	37.7 vs 35.9	10.6 vs 10.1

PFS, progression-free survival; ORR, overall response rate; NA, not available; dox, doxorubicin; cyclo, cyclophosphamide; 5-FU, 5-fluorouracil; mel, melphalan; cis, cisplatin; meth, methotrexate; vin, vinblastin; ifosf, ifosfamide.

years. At 4 years, pelvic, regional and distant recurrence rates were observed to be 2%, 2% and 19%, respectively. Four-year DFS and OS were 81% and 85%, respectively. Grade 2 and 4 late toxicity was seen in 21% of cases and grade 1 and 2 in 57% of cases. The inferences drawn were that this was a feasible regime with acceptable toxicity showing excellent locoregional control, and should be tested in a randomized controlled trial. It has become the basis of the PORTEC 3 trial.

There seems to be a stronger view in favour of adjuvant chemotherapy in locally advanced disease as the risk of distant spread and resultant mortality is high. The response rates to different chemotherapeutic agents used alone range between 4% and 77%. A systematic review of chemotherapy in advanced endometrial carcinoma by Humber et al reported an improvement in OS to 15 months from 6.9 months for best supportive care (Humber et al 2007). Median PFS improved from 3.2 months to 8.3 months. Overall response rates ranged between 17% and 34% for single agents, but between 30% and 69% for combination chemotherapy. Unfortunately, randomized evidence is lacking but retrospective data have shown some improvement in RFS but not OS. A randomized trial of adjuvant chemotherapy with cisplatin and adriamycin has been completed by the European Organization for Research and Treatment of Cancer, and the results are encouraging (Aapro et al 2003). Many oncologists feel uncomfortable not giving adjuvant chemotherapy to this group of patients (FIGO stage IIIA onwards), and treat them with platinum +/- anthracycline/taxane.

Metastatic endometrial cancer carries a very poor prognosis. Palliative treatments range from radiotherapy to hormonal therapy to chemotherapy depending on the symptoms of the patients, comorbidities and their wishes. Cytotoxic options include platinum +/- anthracycline/taxane.

Hormonal therapy

A proportion (11–25%) of endometrial carcinomas express ER and/or PR. Published data do not support the routine use of adjuvant hormones in early-stage disease. This is because of a high rate of recurrence following endocrine treatment in spite of very significant initial complete response rates (Ushijima et al 2007). However, in exceptional circumstances where, due to extreme comorbidities or patient choice, surgery or radiotherapy cannot be used, consideration may be given to the use of hormone treatment. For advanced endometrial carcinomas, especially those that are well differentiated, showing strong progesterone positivity and metastatic to the lungs, hormone therapy is a reasonable choice and should always be considered (Bouros et al 1996, Thigpen et al 1999). Long-term responses have been documented. The most commonly used agent is medroxyprogesterone in high doses such as 200 mg two to three times a day. Fluid retention and heart failure are recognized complications. Other hormonal agents such as aromatase inhibitors have been used with some efficacy (Rose et al 2000).

Uterine Sarcomas

The uterus is not an uncommon site for the development of sarcomas. The principles of management are very similar to those for endometrial carcinomas and soft tissue sarcomas at other sites. The mainstay of treatment is surgery for early and localized disease. Radical radiotherapy can be considered for surgically unfit patients. The common perception of these tumours being radioresistant is only true for leiomyosarcomas.

The indications for adjuvant treatment are somewhat variable but mainly depend on the type of sarcoma, size and degree of surgical clearance. For small (≤ 5 cm) low-grade

sarcomas with complete microscopic clearance, radiotherapy is unnecessary as the risk of local recurrence is low. Similarly, there is insufficient evidence to suggest that radiotherapy is beneficial in cases of endometrial stromal sarcomas. Tumours larger than 5 cm, of higher grade and malignant mixed Müllerian tumours, also known as 'carcinosarcomas', should be considered for adjuvant radiotherapy. Incomplete surgical clearance usually requires higher doses of radiotherapy. Previous history of radiotherapy to the pelvis is very important as this may be a causative factor in some pelvic sarcomas (Nakanishi et al 2001).

Retrospective data suggest no definite survival benefit with adjuvant radiotherapy for early disease, but a significant reduction in the risk of local recurrence. The Royal Marsden experience shows local recurrence rates as high as 70% without radiotherapy. With external beam radiotherapy, the rate of local recurrence fell to 40%, and, with the addition of brachytherapy, fell as low as 23%. Local DFS improved to 70% from 55% with the use of radiotherapy in stage I disease. In stage II and III disease, the best results are achieved with external beam radiotherapy and brachytherapy combined.

Since publication of the meta-analysis of adjuvant chemotherapy in soft tissue sarcoma and the small associated benefit, many oncologists have extrapolated the data to include uterine sarcomas of high grade, especially leiomyosarcomas (Sarcoma Meta-analysis Collaboration 2000). More recent updates have only shown a marginal benefit against significant toxicity (Pervaiz et al 2008). Doxorubicin and ifosfamide are given as a three-weekly cycle to a total of six. Common side-effects include nausea and vomiting, hair loss, cardiotoxicity, confusion and neutropenic sepsis. Another challenge is the management of malignant mixed Müllerian tumours. The prognosis of this aggressive subtype remains very poor, with 3-year OS of approximately 22%. The only randomized trial of cisplatin and ifosfamide that showed some benefit also revealed that the toxicity was quite significant (Sutton et al 2000, 2005). Although the use of adjuvant chemotherapy is gradually increasing, there is, as yet, no set standard. The relatively low incidence of these tumour types and frailty of many patients makes it difficult to plan randomized trials.

Recurrent disease might be localized in a small proportion of cases. The history of previous treatments, relapse-free interval, distribution of the disease and comorbidities determine further management which may include localized surgery to exenterative surgery to radical radiotherapy or only palliative measures. For metastatic disease, the goal is palliation at the outset. Radiotherapy for localized symptoms, chemotherapy for more widespread disease, occasionally surgery for intractable local symptoms, and even hormonal treatment with progestogens for low-grade endometrial stromal sarcomas have a place.

Prognosis

The aura of good prognosis surrounding endometrial cancer may just be a reflection of diagnosis and prompt treatment at an early stage. The prognosis for advanced-stage disease is quite poor, with the exception of metastatic disease responsive to progestogens. In this situation, years of control can

sometimes be achieved with very significant improvement of symptoms. Although hormone-resistant disease may respond to chemotherapy, the responses are short-lived. Aggressive/high-risk histologies also carry a poorer prognosis (Table 42.6).

Stage IC poorly differentiated endometrioid, papillary serous and clear cell tumours have 5-year survival rates of 50–70% (Murphy et al 2003, Havrilesky et al 2007b). Uterine sarcomas are also aggressive histiotypes, but the prognosis ranges from approximately 30% OS for malignant mixed Müllerian tumours (Callister et al 2004) to 50–90% for endometrial stromal sarcomas (Chan et al 2008). Leiomyosarcomas probably fall in the middle, with a 5-year survival rate of 40% (Kahanpaa et al 1986) (Box 42.4).

Targeted Therapies

Currently, approximately 250 clinical trials involving endometrial cancer are registered internationally. Fifty-nine of these include some form of targeted therapy. These studies focus almost exclusively on recurrent or persistent disease. Agents are used as monotherapy or in combination with chemo- or radiotherapy, and also with other targeting agents.

Forty-six trials cover three groups of agents: tyrosine kinase receptor inhibitors or antibodies ($n = 23$), mTOR (mammalian target of rapamycin) inhibitors ($n = 14$) and oestrogen inhibitors (selective ER modulators, aromatase inhibitors) ($n = 9$). The remaining 13 trials include agents such as cell cycle inhibitors, mitogen-activated protein

Box 42.4 Staging system for uterine sarcomas

Stage I	Sarcomas confined to the uterus
Stage II	Sarcomas involving the corpus and cervix
Stage III	Sarcomas spreading beyond the uterus but not outside the pelvis
Stage IV	Sarcomas spreading outside the pelvis or into the bladder or rectum

kinase inhibition, gonadotrophin-releasing hormone agonism, folic acid analogism, histone deacetylase inhibition, the monoclonal antibody RAV12, CALAA-01 (RNA interference), UCN-01 (protein kinase C inhibition) and cyclo-oxygenase II inhibition.

Amongst these, the most widely researched molecules are the epidermal growth factor receptor and the vascular endothelial growth factor (VEGF) receptor families. The growth and progression of tumours is unequivocally angiogenesis dependent. The main proangiogenic factor, namely VEGF, also known as 'vascular permeability factor', is a potent angiogenic cytokine that induces mitosis and also regulates the permeability of endothelial cells. VEGF is an endothelial-cell-specific growth factor and the principal regulator of angiogenesis under normal and pathological conditions in most organs. Increased levels of VEGF and angiogenic markers are associated with poor outcome in endometrioid endometrial cancer patients (Kamat et al 2007).

The human epidermal growth factor receptor-2 (HER-2 protein), which is also known as *c-erbB-2* or *neu*, is a member of subclass 1 of the superfamily of receptor tyrosine kinases. HER-2 is an independent prognostic factor in endometrial cancer and an important oncogene in high grade and stage endometrial cancer (Morrison et al 2006). Overexpression of HER-2/*neu* was associated with an overall worse prognosis in uterine papillary serous cancer (Slomovitz et al 2004). Inhibition of the epidermal growth factor receptor in poor prognostic types of endometrial cancer may be of benefit. There is limited research into new therapies for endometrial cancer, despite the increasing incidence. Identification of new drugs and targeted therapies for poor prognostic types of endometrial cancer will benefit treatment at initial presentation and relapse.

Follow-Up in Endometrial Cancer

Recurrence from endometrioid endometrial cancer tends to be pelvic and frequently occurs at the vaginal vault, usually within the first 2 years after diagnosis. In patients who have

received adjuvant radiotherapy, recurrences can be sited outside the radiotherapy field. Recurrence in sarcomas can be distant and occur in the chest. Vaginal bleeding and discharge is the most common presentation at relapse. During follow-up, symptoms such as vaginal bleeding and/or discharge, and any urinary or gastrointestinal disturbance should raise the suspicion of relapse and prompt appropriate investigation. The history should also aim to identify morbidity associated with radiotherapy, such as troublesome diarrhoea which can be managed with the use of codeine or over-the-counter medication. Vaginal dilators are also beneficial to preserve vaginal capacity after radiotherapy in patients keen to preserve vaginal capacity, and also to aid clinical examination at follow-up. An abdominal examination and vaginal examination to detect vaginal/pelvic masses is of value. Patients with early-stage endometrial cancer stage IA with grade 1 endometrioid cancer can be discharged safely. All patients with poor prognostic types of histology and patients who have received adjuvant radio-/chemotherapy should be seen at regular intervals for the first 2 years and then less frequently in the subsequent 3 years after diagnosis. The value of clinician-led follow-up compared with patient-initiated follow-up in the presence of symptoms for early-stage endometrial cancer has never been proven. However, it remains conventional practice to institute a regime of follow-up for patients at greatest risk of recurrence. HRT can be safely instituted in symptomatic young women with adequately staged and treated stage I endometrial cancer.

Challenges and Future Directions

The rising incidence in endometrial cancer is likely to continue and this will impact on current resources. Laparoscopic surgery will become more established in the management of this disease, as will tailoring adjuvant therapy for those at greatest risk of recurrence. Results of trials of targeted therapies in poor prognostic types of endometrial cancer are eagerly awaited, and may pave the way for individualization of treatment in the future.

KEY POINTS

1. The incidence of endometrial cancer is increasing, attributable to an increase in obesity, adjuvant tamoxifen therapy in breast cancer and life expectancy.
2. Endometrial cancer can be characterized on molecular pathology into an oestrogen-dependent type I, comprising well to moderately differentiated endometrioid histologies, and non-oestrogen-dependent type II, comprising grade 3 endometrioid, uterine serous papillary cancer, clear cell carcinoma and carcinosarcoma.
3. The diagnosis of endometrial cancer is made by a pipelle sample or hysteroscopically obtained endometrial biopsy.
4. Surgical treatment of early-stage endometrial cancer is the mainstay of treatment, followed by adjuvant radiotherapy in selected cases based on the risk of recurrence.
5. Laparoscopic surgery is feasible and safe in women with endometrial cancer, and may reduce the morbidity associated with surgery in obese women.
6. Early-stage endometrial cancer can be classified into low risk, intermediate risk and high risk based on the risk of recurrence.
7. For low-risk endometrial cancers, adjuvant radiotherapy can be safely omitted. External beam radiotherapy for intermediate-risk patients can be confined to patients over 60 years of age with lymphovascular invasion on histology.
8. External beam radiotherapy to the pelvis in intermediate-risk patients reduces the risk of recurrence but does not improve survival.
9. The optimum adjuvant therapy for patients with high-risk endometrial cancer is currently not known and is being investigated.
10. Pelvic lymphadenectomy in intermediate–high-risk endometrial cancer does not confer survival benefit, but knowledge of lymph node status enables accurate staging. This may have an impact on selecting patients for adjuvant therapy, and thereby reducing morbidity from external beam radiotherapy.

Introduction

The World Health Organization (WHO) has classified gestational trophoblastic disease (GTD) into two premalignant diseases, termed 'complete hydatidiform mole' (CM) and 'partial hydatidiform mole' (PM), and three malignant disorders, termed 'invasive mole', 'gestational choriocarcinoma' and 'placental-site trophoblastic tumour' (PSTT) (World Health Organization 1983). These malignant disorders are also frequently referred to as 'gestational trophoblastic tumours' (GTTs) or 'neoplasia' (GTN). GTTs are important to recognize because they are nearly always curable and fertility can be preserved in most cases. This is mainly because:

- GTTs are exquisitely chemosensitive;
- all GTTs produce human chorionic gonadotrophin (hCG), a serum tumour marker with a sensitivity and accuracy in screening, monitoring, management and follow-up of patients which is unparalleled in cancer medicine; and
- detailed prognostic scoring has permitted fine-tuning of treatment intensity so that each patient only receives the minimum therapy required to eliminate her disease.

Genetics and Pathology

Complete hydatidiform mole

CMs nearly always contain paternal DNA alone and are therefore androgenetic. This occurs in most cases because a single sperm bearing a 23X set of chromosomes fertilizes an ovum lacking maternal genes, and then duplicates to form the homozygote, 46XX (Figure 43.1A). However, in up to 25% of CMs, fertilization can take place with two spermatozoa, resulting in the heterozygous 46XY or 46XX configuration (Figure 43.1B). A 46YY conceptus has not yet been described and is presumably non-viable. Very rarely, a CM can arise from a fertilized ovum which has retained its maternal nuclear DNA and is therefore biparental in origin (Fisher and Newlands 1998). Macroscopically, the classic CM resembles a bunch of grapes due to generalized (complete) swelling of chorionic villi. However, this appearance is only seen in the second trimester and the diagnosis is usually made earlier when the villi are much less hydropic. Indeed, in the first trimester, the villi microscopically contain little fluid, are branching and consist of hyperplastic syncytio- and cytotrophoblast with many vessels. Although it was previously thought that CM produced no fetal tissue, histology from 6–8-week abortions reveals evidence of embryonic

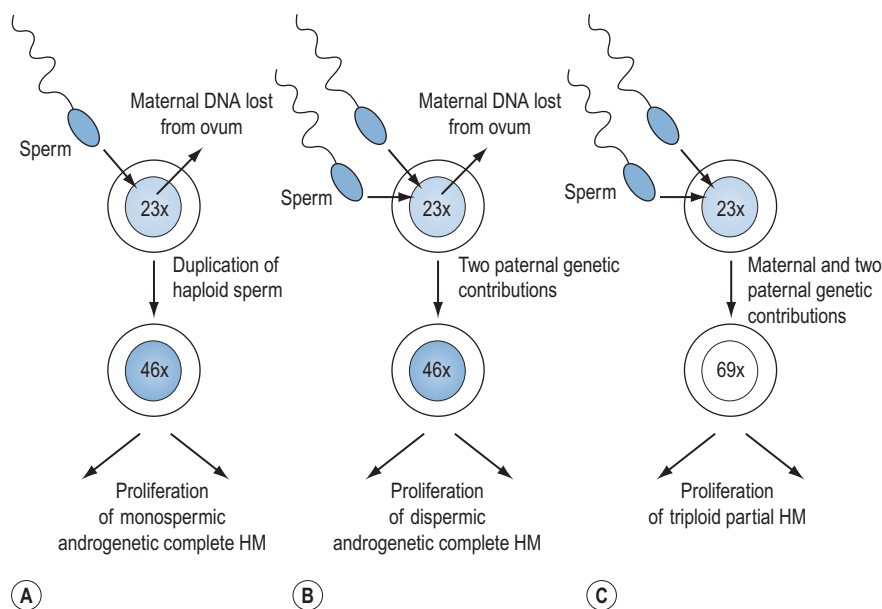

Figure 43.1 Schematic diagram showing that the androgenetic diploid complete hydatidiform mole is formed either (A) by duplication of the chromosomes from a single sperm, or (B) by two sperm fertilizing the ovum which, in both cases, has lost its own genetic component. The triploid genetic origin of a partial hydatidiform mole (HM) is demonstrated in (C).

elements, including fetal red cells (Paradinas 1998). This has resulted in pathologists incorrectly labelling CMs as PMs. The presence of embryonic tissue from a twin pregnancy comprising a fetus and a CM is another source of error which can lead to the incorrect diagnosis of PM.

Partial hydatidiform mole

Genetically, PMs are nearly all triploid with two paternal and one maternal sets of chromosomes (Figure 43.1C). Rarely, tetraploid PMs are found. Triploidy occurs in 1–3% of all recognized conceptions and in approximately 20% of spontaneous abortions with an abnormal karyotype, but at least two paternal sets of chromosomes are needed for PM development. Triploids due to two sets of maternal chromosome do not become PMs (Lawler et al 1982). Although a variety of reports have suggested that diploid PMs exist, genetic analysis of such lesions has not supported this. In general, a diploid molar gestation is believed to be a CM (Genest et al 2002). Flow cytometry, which can be done in formalin-fixed, paraffin-embedded tissues (Seckl et al 2000), can help in differentiating CM from PM, and PM from diploid non-molar hydropic abortions.

In PMs, villous swelling is less intense and only affects some villi. Both swollen and non-swollen villi can have trophoblastic hyperplasia which is mild and focal. The villi have characteristic indented outlines and round inclusions. An embryo is usually present and can be recognized macroscopically or inferred from the presence of nucleated red cells in villous vasculature. It may survive into the second trimester, but usually dies at approximately 8–9 weeks of gestation and this is followed by loss of vessels and stromal fibrosis. In PMs evacuated early, villous swelling and trophoblastic excess can be so mild and focal that the diagnosis of PM may be missed (Paradinas 1998). Indeed, at uterine evacuation for a 'miscarriage', it is likely that many PMs are misclassified as products of conception. Fortunately, the authors only see about one patient per year with persistent GTD related to a previously unrecognized PM. Of the increas-

ing number of PMs which are correctly diagnosed, very few go on to develop persistent GTD. Indeed, in approximately 3000 PMs reviewed and followed at Charing Cross Hospital between 1973 and 1997, only 15 (0.5%) have required chemotherapy (Seckl et al 2000).

Other pregnancies mistaken for hydatidiform mole

Over half of first-trimester non-molar abortions are due to trisomy, monosomy, maternally derived triploidy and translocations. These often develop hydrops but are small (<3 mm), and PM can be excluded if they are diploid on flow cytometry. A significant recent development in the pathological analysis of hydatidiform mole (HM) is the use of *p57^{kip2}* immunostaining to make a definitive diagnosis of androgenetic CM as opposed to a hydropic abortion or a PM. *p57^{kip2}*, a cyclin-dependent kinase inhibitor, is a paternally imprinted gene which is maternally expressed. The absence of maternal genes in androgenetic CM means that the gene cannot be expressed in CM cytotrophoblast. Consequently, *p57^{kip2}* staining is negative with CMs, in contrast to PMs, hydropic abortion and normal placenta. This technique is well validated, easy and inexpensive to perform (Sebire et al 2004, Popiolek et al 2006).

Syndromes such as Turner's, Edward's and Beckwith-Wiedemann's can also cause histological confusion with PMs (Paradinas 1998).

Invasive hydatidiform mole

Invasive hydatidiform mole is common and is clinically identified by the combination of an abnormal uterine ultrasound (US) and a persistent or rising hCG level following uterine evacuation of a CM or PM. Pathological confirmation of this condition is rarely required. Moreover, repeat dilatation and curettage (D & C) is often contraindicated because of the risks of uterine perforation, infection,

life-threatening haemorrhage and subsequent hysterectomy. In occasional cases where histology is available, invasive mole can be distinguished from choriocarcinoma by the presence of chorionic villi. Identification of cases of CM and PM that will subsequently undergo malignant transformation would be an important development. There is accumulating evidence that such HMs are more likely to show telomerase activity (i.e. have limitless replicative potential) and increased expression of the anti-apoptotic gene *Mcl-1* (Wells 2007). These findings need further prospective evaluation.

Choriocarcinoma

Most choriocarcinomas have been shown to have grossly abnormal karyotypes with diverse ploidies and several chromosome rearrangements, none of which are specific for the disease (Arima et al 1994). Studies of the origin of GTTs have confirmed that choriocarcinoma may arise from any type of pregnancy including a normal term pregnancy, or homozygous or heterozygous CM. Until recently, it was thought that PMs could not give rise to choriocarcinoma. However, there is now incontrovertible genetic evidence that PMs can indeed transform into choriocarcinomas (Seckl et al 2000). This is important as some centres wrongly believe that it is safe to discontinue hCG follow-up following the diagnosis of a PM.

Interestingly, choriocarcinoma may not always be due to the antecedent pregnancy. A patient with a history of CM 4 years previously developed choriocarcinoma following the delivery of a twin pregnancy. Using polymerase chain reaction to amplify short tandem repeat polymorphisms in DNA, this tumour was shown to be genetically identical to the previous CM (Fisher et al 1995). As for invasive moles, obtaining tissue to make a formal histological diagnosis of choriocarcinoma is often not appropriate, so doubt frequently exists regarding whether patients have one or the other form of GTT.

Choriocarcinoma is highly malignant in behaviour, appearing as a soft, purple, largely haemorrhagic mass. Microscopically, it mimics an early implanting blastocyst with central cores of mononuclear cytotrophoblast surrounded by a rim of multinucleated syncytiotrophoblast and a distinct absence of chorionic villi. There are extensive areas of necrosis and haemorrhage, and frequent evidence of tumour within venous sinuses. Interestingly, the disease fails to stimulate the connective tissue support normally associated with tumours, and induces hypervascularity of the surrounding maternal tissues. This probably accounts for its highly metastatic and haemorrhagic behaviour.

Placental-site trophoblastic tumour

PSTTs have been shown to follow term delivery, non-molar abortion or CM. Furthermore, a recent case has shown that PSTTs can develop after a PM (Palmieri et al 2005). Like choriocarcinoma, the causative pregnancy may not be the immediate antecedent pregnancy (Fisher et al 1995). Genetic analysis of some PSTTs has demonstrated that they are mostly diploid, originating from either a normal conceptus and therefore biparental, or androgenetic and arising from a CM (Newlands et al 1998a).

In the normal placenta, placental-site trophoblast is distinct from villous trophoblast and infiltrates the decidua, myometrium and spiral arteries of the uterine wall. PSTTs are rare, slow-growing malignant tumours composed mainly of intermediate trophoblast derived from cytotrophoblast, and so produce little hCG. However, they often stain strongly for human placental lactogen (hPL) and β 1-glycoprotein. Elevated Ki-67 levels may help in distinguishing PSTTs from regressing placental nodules (Shih and Kurman 1998). In contrast to other forms of GTT, spread tends to occur late by local infiltration and via the lymphatics, although distant metastases can occur. More than five mitoses per 10 high-power fields may predict tumours with metastasizing potential (Newlands et al 1998a).

Epithelioid trophoblastic tumour

Epithelioid trophoblastic tumours (ETT) are a recently described neoplastic proliferation of intermediate trophoblast that are thought, by some investigators, to be distinct from PSTTs and choriocarcinoma. It has been proposed that ETTs arise from the intermediate trophoblasts of the chorionic laeve (Shih and Kurman 2001). Histologically, ETTs display a relatively uniform, nodular proliferation of intermediate-sized epithelioid trophoblasts, forming nests and cords. Islands of trophoblast are typically surrounded by areas of hyalinization or eosinophilic debris simulating tumour cell necrosis and resembling keratinous material in a squamous cell carcinoma. ETTs can be associated with focal replacement of the cervical glandular epithelium with stratified neoplastic cells, simulating squamous cervical intraepithelial neoplasia. ETT cells are positive for cytokeratin, epithelial membrane antigen and inhibin-A, whereas trophoblastic markers hPL, hCG and melanoma cell adhesion molecular are only expressed focally (Hui et al 2005).

Whether ETT is really a distinct disease entity in the GTD spectrum remains a contentious issue. Indeed, the authors have only seen this appearance in patients who have previously had chemotherapy for an invasive mole or choriocarcinoma, so this may simply represent the differentiating effects of treatment (as seen with germ cell tumours) rather than a separate type of GTT.

Epidemiology and Aetiological Factors

Hydatidiform mole

Incidence and ethnic origin

The incidence of HM in the UK is one in 714 pregnancies (Tham et al 2003). Recent results indicate that the previously documented higher rates in the Far East have fallen towards the stable levels found in Europe and North America (Hando et al 1998), possibly because of dietary changes. The incidence of PM has been underestimated in the past and is currently three per 1000 pregnancies (Newlands et al 1998b).

Age

CMs are more common at the extremes of reproductive age. In one study, compared with the lowest rate between 25–29 years, the relative increased risk was six-fold in girls under

15 years, three-fold between 40 and 45 years, 26-fold between 45 and 49 years and more than 400-fold over 50 years of age (Bagshawe and Begent 1983, Newlands et al 1998b). PMs are also more common at the extremes of reproductive age, although the effect is less pronounced (Sebire et al 2002a).

Previous pregnancies

Increasing gravidity does not increase the risk of CM. However, following one CM, the risk of a subsequent pregnancy being a CM rises from one in 1000 to one in 76, and to one in 6.5 with two previous CMs (Bagshawe and Begent 1983). Therefore, patients with a previous CM must be followed-up after each subsequent pregnancy to confirm that their hCG levels return to normal. Similar results have been reported for PMs, with the risk for subsequent molar pregnancies rising to one in 59 for women with one previous PM (Sebire et al 2003).

Choriocarcinoma

The incidence of choriocarcinoma following term delivery without a history of CM is approximately one in 50,000. However, CM is probably the most common antecedent to choriocarcinoma, comprising 29–83% in various studies across the world (World Health Organization 1983). Consequently, the overall incidence of choriocarcinoma after a CM is much higher. Proof of this is frequently difficult to obtain, but when histology was available, these tumours were identified as choriocarcinoma in 3% and invasive mole in 16% of previous CMs (seldom as PSTT). Rarely, PMs can give rise to choriocarcinoma (Seckl et al 2000). Unlike HM, choriocarcinoma does not exhibit any clear geographical trends in incidence, but the effect of age remains important.

Placental-site trophoblastic tumours

First described as a separate disease entity in 1976 (Kurman et al 1976), there are currently approximately 150 recorded cases of this tumour in the literature; therefore, estimates of its true incidence may be quite inaccurate (Newlands et al 1998a, Papadopoulos et al 2002, Hassadia et al 2005, Baergen et al 2006). In the largest series described — 62 patients between 1976 and 2006 — PSTTs represented 0.2% of all trophoblastic tumours (Schmid et al 2008). The relative incidence in the UK has been stable over the past 15 years following an increase in the first years after the introduction of this new disease classification.

Genetic Factors: The Role of Imprinting

Hydatidiform mole

The theory of an underlying genetic cause of HM is based on two observations: women who have had one mole have an excess risk of having another mole; and the discovery of an inherited syndrome of recurrent CM pregnancies, which has been identified in a handful of families globally. Familial CM is diagnosed by the presence of more than one woman in a single family with two CMs or more, and is inherited in

an autosomal-recessive pattern. These families are being studied with the aim of identifying specific genetic abnormalities and their role in the pathogenesis of HM.

All autosomal genes consist of two alleles (paternal and maternal). However, some alleles are only expressed from one parent and not the other; a phenomenon called 'genomic imprinting'. Underexpression of an imprinted gene has been demonstrated in cases of both familial and sporadic CM, and abnormal methylation patterns have been described in another family (Fisher et al 2002, Judson et al 2002).

Extensive mapping studies have been performed on the families with CM. These have demonstrated a defective locus at 19q13.4 in five families which has been localized to a single gene — *NALP7* (Murdoch et al 2006). This is the first causative single gene defect identified in CM. *NALP7* is a member of the CATERPILLER family which is involved in inflammation and apoptosis. It is expressed in oocytes and the endometrium, and is a negative regulator of the proinflammatory cytokine interleukin-1 β , which is involved in regulating trophoblast invasion during implantation. It is unclear how defects in *NALP7* result in CM formation, but abnormal inflammation during embryogenesis may be involved.

NALP7 does not appear to be involved in the establishment of imprinting; therefore, defects in *NALP7* may be a consequence of abnormal imprinting rather than its cause. Further families have been identified that do not map to 19q13.4, proving that familial CM is a genetically heterogeneous condition (Zhao et al 2006). Moreover, to date, abnormal *NALP7* has not been demonstrated in sporadic CM or PM cases.

Three other, closely related, genes are imprinted and may be involved in GTT development. These are *H19*, a putative tumour suppressor gene (Hao et al 1993), and *p57^{kip2}* (discussed previously) (Matsuoka et al 1996), both of which are normally expressed by the maternal allele; and the paternally expressed *IGF-2*, a growth factor commonly implicated in tumour proliferation (Ogawa et al 1993). While *p57^{kip2}* showed the expected pattern of expression in CM and choriocarcinoma (Chilosi et al 1998), CM and postmole tumours were unexpectedly found to express *H19* (Walsh et al 1995), and some post-term tumours showed biallelic expression of both *H19* and *IGF-2* (Hashimoto et al 1995). This suggests that loss of the normal imprinting patterns of these genes may be an important factor in the development of GTT.

Choriocarcinoma

Historically, cytogenetic studies of choriocarcinoma have demonstrated a diverse range of abnormalities. Microsatellite studies have shown loss of heterozygosity at specific regions: deletions of 7p12-q11.2, amplification of 7q21-q31 and loss of 8p12-p21 (Matsuda et al 1997). Abnormalities in the latter two are also found in some cases of ovarian and breast cancer, and are postulated to encode novel tumour suppressor genes. Several groups have reproduced these findings in non-molar choriocarcinoma, but results in postmolar choriocarcinoma have been inconsistent (Burke et al 2006). Only a minority of tumours showed loss of heterozygosity for all three regions, suggesting that these defects are acquired late in the development of choriocarcinoma and are not essential for malignant transformation.

Risk of Gestational Trophoblastic Tumours Following Complete or Partial Hydatidiform Mole

Following evacuation of a CM or PM, the risk of developing a GTT is less than 16% and 0.5%, respectively (Bagshawe et al 1990, Seckl et al 2000). Since it is not yet possible to predict which patients with a CM or PM will develop persistent GTD, all patients must be registered for hCG monitoring. Following this strict protocol enables the identification of individuals with persistent trophoblastic growth who could benefit from life-saving chemotherapy.

Human Chorionic Gonadotrophin

Beta-human chorionic gonadotrophin assays

The family of pituitary/placental glycoprotein hormones includes hCG, follicle-stimulating hormone, luteinizing hormone (LH) and thyroid-stimulating hormone (TSH). Each hormone comprises an α -subunit which is common between the family members and a distinct β -subunit. Consequently, assays to measure hCG are directed against the β -subunit. Many different β -hCG assays are available. Some detect intact β -hCG, and others are either selective for individual fragments or detect various combinations of fragments (Cole 1998). In pregnancy, hCG is usually intact and fragments of β -hCG are not produced, although the β chain is hyperglycosylated during the first trimester. However, in cancer, β -hCG may circulate in many different forms which can vary in their glycosylation status. Therefore, assays used in patients with GTD and cancer need to be able to detect all forms of β -hCG. The ideal assay should be able to recognize all forms equally well and be sufficiently sensitive to limit the risk of false-negative results (Mitchell and Seckl 2007). Moreover, the assay should not produce false-positive results as this is well recognized to be associated with unnecessary medical interventions and potentially life-threatening complications (Cole et al 2001). So how good are the existing β -hCG assays?

Commercially available β -hCG tests are based on the sandwich assay principle and rely on two antibodies which generally target different regions of the molecule. These assays are primarily licensed for use in pregnancy detection. However, they are frequently employed for monitoring patients with cancer. The assays can produce both false-positive and false-negative results (Cole et al 2001, Mitchell and Seckl 2007). The false-positive results occur because there is another molecule (often a heterophile antibody) which sticks the capture and detection antibodies together. This can usually be avoided by measuring the hCG in urine, as cross-reacting antibodies are large and cannot pass through the renal glomerulus into the urine. Alternatively, if a false-positive result is suspected, remeasuring the hCG on an alternative assay or serially diluting the serum sample usually resolves the issue. Real hCG will be seen in another assay and will dilute appropriately, whilst a cross-reacting molecule will be negative in another assay and does not serially dilute away. Recent work from the authors' laboratory shows that commercial assays may be particularly prone to false-negative results, either because they completely fail to detect or as a

consequence of poor sensitivity for a particular β -hCG isoform (Mitchell and Seckl 2007). False-negative results can potentially result in failure to diagnose disease or early termination of treatment, and therefore higher relapse rates.

In addition to the commercial assays, there are also several in-house assays in various centres around the world which are usually based on a single antibody to capture the hormone on a competitive basis with labelled (often radioactively) β -hCG. These assays may also produce false-positive and false-negative results. Indeed, all types of assay are only as good as the antibodies used. At Charing Cross Hospital, a rabbit polyclonal antibody is used in a radioimmunoassay (RIA); this recognizes all forms of β -hCG equally well and with sufficient sensitivity that false-negative results appear to be rare (Mitchell and Seckl 2007). Moreover, since this RIA is performed on both serum and urine samples which are serially diluted, the risk of false-positive results is very low (Mitchell and Seckl 2007).

Currently, the authors believe that the Charing Cross RIA for β -hCG remains the gold standard assay for use in the management of GTD and other cancers. The assay is sensitive to 1 IU/l in serum and 20 IU/l in urine.

New assays designed to detect specific hCG variants are in development and are leading to further increases in the specificity and sensitivity of hCG monitoring. Elevation of hyperglycosylated hCG (hCG-H) levels may be specific to cases of HM that subsequently require chemotherapy. This rise occurs earlier than in conventional hCG and before clinically apparent GTTs develop (Cole et al 2006a). However, further work is required, and since no commercial hCG-H assays are available, progress in this area is likely to be slow.

Recent data have also shown that proportionately higher levels of free β -hCG fragments are produced in PSTTs, and that this is a highly sensitive test for discriminating PSTTs from choriocarcinoma (Cole et al 2006b, Harvey et al 2008), although β -hCG may also be elevated in some non-trophoblastic malignancies.

Beta-human chorionic gonadotrophin as a tumour marker

hCG has a half-life of 24–36 h and is the most sensitive and specific marker for trophoblastic tissue. However, hCG production is not confined to pregnancy and GTD. Indeed, hCG is produced by any trophoblastic tissue found, for example, in germ cell tumours and in up to 15% of epithelial malignancies (Vaitukaitis 1979). The hCG levels in such cases can be just as high as those seen in GTD or in pregnancy. Therefore, measurements of hCG do not reliably discriminate between pregnancy, GTD or non-gestational trophoblastic tumours.

However, serial measurements of hCG have revolutionized the management of GTD for several reasons. The amount of hCG produced correlates with tumour volume, such that a serum hCG level of 5 IU/l corresponds to approximately 10^4 – 10^5 viable tumour cells. Consequently, these assays are several orders of magnitude more sensitive than the best imaging modalities available today. In addition, hCG levels can be used to determine prognosis (Bagshawe 1976). Serial measurements allow monitoring of disease progression or response to therapy (Figure 43.2). Develop-

Figure 43.2 Graph demonstrating the use of monitoring the serum human chorionic gonadotrophin (hCG) concentration following evacuation of a hydatidiform mole (HM). In this case, after an initial fall, the hCG level started to rise, indicating the development of invasive HM or choriocarcinoma, so the patient was called up for staging. The prognostic score was low risk (see Table 43.4) and the patient was successfully treated with methotrexate (MTX) and folinic acid (see Table 43.5).

ment of drug resistance can be detected at an early stage, which facilitates appropriate changes in management. Estimates may be made of the time for which chemotherapy should be continued after hCG levels are undetectable in serum in order to reduce the tumour volume to zero. For these reasons, hCG is the best tumour marker known.

Clinical Features

Complete and partial moles

These most commonly present in the first trimester as a threatened abortion with vaginal bleeding. If the diagnosis is delayed, patients may notice the passing of grape-like structures (vesicles), and occasionally the entire mole may be evacuated spontaneously. The uterus may be any size but is commonly large for gestational age. Patients with marked trophoblastic growth and high hCG levels are particularly prone to hyperemesis, toxæmia and the development of theca lutein cysts which may sometimes be palpable above the pelvis. Toxæmia was diagnosed in 27% of patients with CM (Berkowitz et al 1981), but is seen less frequently today because of early US diagnosis. Convulsions are rare. The high hCG levels may also produce hyperthyroidism because of cross-reactivity between hCG and TSH at the TSH receptor. Although pulmonary, vaginal and cervical metastases can occur, they may disappear spontaneously following removal of the mole. Thus the presence of metastases does not necessarily imply that an invasive mole or choriocarcinoma has developed. Patients may rarely present with acute respiratory distress, not only because of pulmonary metastases or anaemia but occasionally as a result of tumour embolization (Savage et al 1998). The risk of embolization is reduced by avoiding agents which induce uterine contrac-

tion before the cervix has been dilated to enable evacuation of the CM.

Patients with PMs do not usually exhibit the dramatic clinical features characteristic of CM (Goldstein and Berkowitz 1994). The uterus is often not enlarged for gestational age, and vaginal bleeding tends to occur later so that patients most often present in the late first or early second trimester with a missed or incomplete abortion. In fact, the diagnosis is often only suspected when the histology of curettings is available. The pre-evacuation hCG level is less than 100,000 IU/l at diagnosis in over 90% of cases.

At present, a proportion of CMs and PMs still go undiagnosed because of miscarriage at home or because termination centres do not carry out histopathological examination of all abortions (Seckl et al 2004a). This can result in late presentation of disease, sometimes with life-threatening complications. Clearly, there is little that can be done about miscarriages at home. However, for women attending termination centres, it may be possible to establish a screening procedure to help prevent subsequent problems from missed diagnosis.

Twin pregnancies

Twin pregnancies comprising a normal fetus and an HM occur in between one in 20,000 and one in 100,000 pregnancies. Some probably abort in the first trimester and so go undiagnosed. However, some are discovered on US examination either routinely or because of complications such as bleeding, excessive uterine size or problems related to a high hCG level. With specialist obstetric care, 40% of such cases have continued into the third trimester and delivered live babies (Sebire et al 2002b).

Invasive moles

Invasive moles are usually diagnosed because serial urine or serum hCG measurements reveal a stable or rising hCG level in the weeks after molar evacuation. Patients may complain of persistent vaginal bleeding and lower abdominal pains and/or swelling. This may occur as a result of haemorrhage from leaking tumour-induced vasculature as the trophoblast invades through the myometrium, or because of vulval, vaginal or intra-abdominal metastases. The tumour may also involve other pelvic structures, including the bladder or rectum, producing haematuria or rectal bleeding, respectively. Enlarging pulmonary metastases or tumour emboli growing in the pulmonary arteries can contribute to life-threatening respiratory complications (Seckl et al 1991). The risk of these complications is clearly higher in patients where the initial diagnosis of a molar pregnancy was missed and who are not, therefore, on hCG follow-up.

Choriocarcinoma

Choriocarcinoma can present after any form of pregnancy, but most commonly occurs after a CM. Histological proof of choriocarcinoma is not usually obtained after a CM because of the risk of fatal haemorrhage caused by biopsy, and so it is impossible to distinguish from an invasive mole. Choriocarcinoma following a normal pregnancy or non-molar abortion usually presents within 1 year of delivery but

can occur 17 years later (Tidy et al 1995). The presenting features may be similar to HM with vaginal bleeding, abdominal pain and a pelvic mass.

However, one-third of all choriocarcinomas present without pelvic symptoms but have symptoms from distant metastases. In these cases, lives can be saved by remembering to include choriocarcinoma in the differential diagnosis of metastatic malignancy (particularly in lungs, brain or liver) presenting in a woman of childbearing age. Any site may be involved, including skin (producing a purple lesion), cauda equina and the heart. Pulmonary disease may be parenchymal, pleural or may result from tumour embolism and subsequent growth in the pulmonary arteries (Savage et al 1998). Thus, respiratory symptoms and signs can include dyspnoea, haemoptysis and pulmonary artery hypertension. Cerebral metastases may produce focal neurological signs, convulsions, evidence of raised intracranial pressure, and intracerebral or subarachnoid haemorrhage. Hepatic metastases may cause local pain or referred pain in the right shoulder. Although none of these presentations are specific to choriocarcinoma, performing a simple pregnancy test or quantitative hCG assay can provide a vital clue to the diagnosis.

Infantile choriocarcinoma

Choriocarcinoma in the fetus or newborn is exceptionally rare, with approximately 30 reported cases (Blohm and Gobel 2004, Sebire et al 2005). While a primary choriocarcinoma within the infant is possible, the mother also had the tumour in 17 cases. Interestingly, the diagnosis was often made in the neonate before the mother. In all cases, the infant was anaemic and had a raised hCG level, but the site of metastasis was variable, including brain, liver, lung and skin. Only a few cases have been treated successfully with platinum chemotherapy (Johnson et al 2003), with the rest dying within weeks of the initial diagnosis, which may have been delayed. Consequently, serum or urine hCG levels should be measured in all babies of mothers with choriocarcinoma. As the disease can present up to 6 months after delivery, an argument could be made for serial monitoring of hCG in these infants.

Placental-site trophoblastic tumour

PSTTs grow slowly and can present years after term delivery, non-molar abortion, CM or PM. Unlike choriocarcinoma, PSTTs tend to metastasize late in their natural history, so patients frequently present with gynaecological symptoms alone. In addition to vaginal bleeding, the production of hPL by the cytotrophoblastic cells may cause hyperprolactinaemia which can result in amenorrhoea and galactorrhoea. Rarely, patients can develop nephrotic syndrome, haematuria and disseminated intravascular coagulopathy. Metastases may occur in the vagina, extrauterine pelvic tissues, retroperitoneum, lymph nodes, lungs and brain (Newlands et al 1998a).

Epithelioid trophoblastic tumours

There are currently only a few recorded cases of this recently described tumour in the literature. Although most ETT

patients are women of childbearing age, a significant percentage of women are peri- or postmenopausal with a remote history of pregnancy (Coulson et al 2000). Similar to PSTTs, patients present with vaginal bleeding and low levels of serum β -hCG (<2500 IU/l). In half of the reported cases, tumours arise in the lower uterine segment or cervix, and the distinction from a keratinizing squamous cell carcinoma can sometimes be difficult. Extrauterine locations such as broad ligament as the primary site have also been observed (Kuo et al 2004). Similar to PSTTs, ETTs appear to respond less well to conventional chemotherapy compared with choriocarcinoma. Consequently, management of ETT cases is currently identical to that for PSTT cases, with hysterectomy for localized disease and careful follow-up until more experience of this rare lesion becomes available.

Investigations

Human chorionic gonadotrophin, chest X-ray and pelvic Doppler ultrasound

All patients who are suspected of having GTTs should have an hCG, a chest X-ray and pelvic Doppler ultrasound. The most common metastatic appearance on chest X-ray is of multiple, discrete, rounded lesions, but large solitary lesions, a miliary pattern or pleural effusions can occur (Bagshawe and Noble 1965). Furthermore, tumour emboli to the pulmonary arteries can produce an identical picture to venous thromboembolism, with wedge-shaped infarcts and areas of decreased vascular markings. Pulmonary artery hypertension can cause dilatation of the pulmonary arteries. Routine computed tomography (CT) scanning of the chest does not add anything to the management of these cases.

US and colour Doppler imaging are not diagnostic but highly suggestive of persistent GTD when there is a combination of a raised hCG level, no pregnancy and a vascular mass within the uterus (Figure 43.3). The last is seen in more than 75% of patients at the authors' centre. Detection rates are higher for CM compared with PM, and improve after 14 weeks of gestation (Fowler et al 2006). The uterine volume and uterine artery blood flow correlate with the amount of disease and the degree of abnormal tumour vasculature, respectively. Doppler frequently demonstrates a change in the waveform of the uterine arteries (Figure 43.3). This is attributed to large vascular channels forming in the myometrium, resulting in arteriovenous shunting (Long et al 1992). The uterine artery pulsatility index, an indirect measure of the functional tumour vascularity, has been shown to independently predict the response to chemotherapy in GTTs (Agarwal et al 2002). Furthermore, the increased sensitivity of modern colour Doppler US now reveals abnormal blood vessel encroachment through the myometrium into the endometrium. Although this has not been shown to have prognostic significance, the degree of vascular endometrial encroachment may aid in assessing the risk of major haemorrhage in patients with GTT (Boultebee and Newlands 1995). Interestingly, the vascular abnormalities within the pelvis and uterus can persist long after the disease has been eradicated with chemotherapy. Indeed, patients with repeated vaginal haemorrhage from these vas-

Figure 43.3 Ultrasonography with colour Doppler showing persistent gestational trophoblastic disease following a complete hydatidiform mole within the body and wall of the uterus. Typical vesicular or 'snow storm' appearance of residual molar tissue can be seen within the uterus, together with a rich blood supply through the endometrium and myometrium. There is no evidence of a fetus. Uterine artery pulsatility index showing low values indicative of arteriovenous shunting associated with an abnormal tumour vasculature.

cular malformations may require selective arterial embolization. This is usually successful and does not appear to affect fertility.

Pelvic US can also demonstrate ovarian theca lutein cysts and other ovarian masses. Metastatic spread outside the pelvis, such as to the liver or kidneys, can also be identified and shown to have an abnormal Doppler signal.

Investigation of drug-resistant disease

When patients develop drug-resistant disease, further investigation is required to more accurately define where the residual tumour is located, as resection can be curative. CT of the chest and abdomen together with magnetic resonance imaging (MRI) of the brain and pelvis are often helpful and can detect deposits not previously seen. If the CT and MRI are normal, a lumbar puncture to measure the hCG level in cerebrospinal fluid can be useful to detect disease in the central nervous system (CNS). An hCG level greater than 1:60 of that found in the serum is highly indicative of the presence of trophoblastic disease.

Experimental imaging techniques

Radiolabelled anti-hCG antibodies given intravenously can localize tumours producing hCG when the serum hCG level is more than 100 IU/l (Begent et al 1987). However, both false-positive and false-negative results occur, so anti-hCG scanning should be regarded as complementary to other imaging investigations. More recently, positron emission tomography (PET) has provided a novel approach to image many tumour types using a variety of labels. Whole-body PET has already been reported to distinguish GTT emboli from blood clots in two patients with choriocarcinoma (Hebart et al 1996).

Other case reports demonstrate the potential value of PET in the differential diagnosis of undefined pulmonary nodules or in the localization of disease (Numnum et al 2005, Shaw et al 2005). ¹⁸Fluorodeoxyglucose (FDG)-PET may be used to locate sites of disease in cases showing serological relapse without visible abnormality on conventional imaging (Dhillon et al 2006). However, the role of PET has yet to be confirmed in larger series of patients with GTTs.

Genetic analysis

On some occasions, it can be helpful to perform a comparative genetic analysis of the patient's trophoblastic tumour with their normal tissue and, if available, that of their partner. Thus, if the tumour is suspected of being of non-gestational origin, this can be confirmed by the presence of maternal DNA alone and the complete absence of paternal DNA. Genetic studies can also determine which of several antecedent pregnancies is the causal pregnancy of the current GTT. This can have an impact on determining appropriate therapy and prognosis (Fisher and Newlands 1998, Fisher et al 2007). In addition, genetic studies can help to identify whether a woman with repeated CM pregnancies has the rare biparental variant of CM. The latter condition is rarely compatible with a normal pregnancy, and preimplantation diagnosis is not yet possible. In contrast, a woman with repeated androgenetic CM can be offered in-vitro fertilization and preimplantation selection of unaffected concepti.

Management

Molar evacuation

Evacuation of the uterine cavity using suction gives the lowest incidence of sequelae. When the molar trophoblast invades the myometrium, it is relatively easy to perforate the uterus if a metal curette is used. Medical induction involving repeated contraction of the uterus induced by oxytocin or prostaglandin, or other surgical approaches including hysterectomy or hysterotomy increase the risk of requiring chemotherapy two- to three-fold compared with suction evacuation. This is thought to be because tumour is more likely to be disseminated by uterine contraction and manipulation. For similar reasons, the use of prostanoids to ripen a nulliparous cervix is not recommended, even in nulliparous women (Royal College of Obstetricians and Gynaecologists 2004). If bleeding is severe immediately after suction evacuation, a single dose of ergometrine to produce one uterine contraction may stem the haemorrhage, and does not appear to increase the chance of requiring chemotherapy.

In the past, it has been common practice for gynaecologists to perform a second and sometimes a third evacuation of the uterine cavity in patients with a molar pregnancy. However, the chance of requiring chemotherapy after one evacuation is only 2.4%, but rises markedly to 18% after two evacuations and 81% after four evacuations (Table 43.1). Patients with an hCG plateau or with rising hCG levels are at particularly high risk of this, and 74% require chemotherapy despite undergoing a second evacuation. In addition, high hCG values have been shown to be an indicator

Table 43.1 Correlation between the number of evacuations performed following an hydatidiform mole and the subsequent requirement for chemotherapy at Charing Cross Hospital (1973–1986)

Number of evacuations	Patients not treated	Patients treated	% Patients treated
1	4481	109	2.4
2	1495	267	18
3	106	106	50
4	5	22	81

for low rates of benefit of a second evacuation, with 80% of patients with a preintervention hCG level of more than 5000 IU/l subsequently requiring chemotherapy (Savage and Seckl 2005). However, second evacuations may be useful for symptom control in selected patients with heavy vaginal bleeding in the presence of persisting molar tissue, or curative if the recurrent molar tissue is confined to the uterine cavity, particularly in those with hCG levels below 1500 IU/l (Pezeshki et al 2004). Such cases should be discussed first with the local GTD centre. The use of US control during this procedure may help to reduce the risk of uterine perforation.

Twin pregnancies

At Charing Cross Hospital, there have been 77 confirmed cases of CM with a separate normal conceptus; 25% of these resulted in a live birth, while the remainder had non-viable pregnancies which mostly ended in spontaneous abortions or suction D & Cs. Interestingly, in both the viable and non-viable pregnancies, only 20% of women subsequently needed chemotherapy to eliminate persistent GTD and none of these women died of resistant disease. Furthermore, although the incidence of pre-eclampsia was 5–10% in those continuing their pregnancies, there were no maternal deaths. Thus, it appears reasonably safe to allow patients with twin pregnancies in which one of the conceptions is a CM to continue to term provided that there are no other complications. This is in line with observations on singleton CMs which suggest that later gestational age at termination does not increase the risk of subsequently requiring chemotherapy (Seckl et al 2004b).

Registration and follow-up after uterine evacuation

The majority of patients require no further treatment after evacuation, but 16% of patients with a CM and less than 0.5% with a PM develop persistent GTD. It is vital that patients with persistent GTD are identified as virtually all of them can be cured with appropriate therapy.

In 1973, under the auspices of the Royal College of Obstetricians and Gynaecologists, a national follow-up service was instituted in the UK whereby patients with GTD are registered with one of three laboratories located in Dundee, Sheffield and London. Approximately 1400 women are registered per annum and 110–120 require subsequent chemotherapy. After registration, the patient's details and pathology, together with two weekly blood and urine samples, are

sent through the post to one of the reference laboratories for confirmation of diagnosis and serial hCG estimations. Following the success of this scheme, other countries have now established or are attempting to establish a similar registration programme to reduce GTT mortality rates.

In the majority of cases, the molar tissue dies out spontaneously, the hCG concentration returns to normal (= 4 IU/l) and the patient can start a new pregnancy after a further 6 months. If the hCG level has fallen to normal within 8 weeks of evacuation, marker follow-up can be safely reduced to 6 months as 98% of patients requiring chemotherapy presented within this timeframe (Sebire et al 2007). Since patients who have had a previous mole or GTT are at greater risk of having another, all patients should have a further estimation of hCG at 6 and 10 weeks following the completion of each subsequent pregnancy.

Indications for chemotherapy

Factors associated with an increased risk of requiring chemotherapy are summarized in Table 43.2. The hormones in the oral contraceptive pill are probably growth factors for trophoblastic tumours; for this reason, patients are advised not to use the pill until hCG levels have returned to normal.

The indications for intervention with chemotherapy in patients who have had a CM or PM are shown in Box 43.1. An hCG value = 20,000 IU/l 4 weeks after evacuation of a mole or rising values in this range at an earlier stage indicate that the patient is at increased risk of severe haemorrhage or uterine perforation with intraperitoneal bleeding. These complications can be life-threatening and their risk can be reduced by starting chemotherapy. Withholding chemotherapy from women with metastases in the lung, vulva and vagina is only safe if the hCG levels are falling. However, chemotherapy is required if the hCG levels are not dropping or if the patient has metastases at another site, which can indicate the development of choriocarcinoma.

Prognostic factors: scoring vs International Federation of Gynaecology and Obstetrics staging

The principal prognostic variables for GTTs, which were originally identified by Bagshawe in 1976 and since modified by WHO and the authors' own experience, are summarized in Table 43.3. Anatomical staging systems, such as that of the International Federation of Gynaecology and Obstetrics (FIGO), have been used by several centres managing GTTs. However, surgery is virtually never indicated in the

initial management of this disease, so the FIGO system does not appear to add anything in treatment planning to the existing scoring system. Furthermore, the original FIGO staging system did not always predict prognosis correctly, so some patients were under- or overtreated (Smith et al 1992). This problem was overcome by modifying the FIGO system

Box 43.1 Indications for chemotherapy following the diagnosis of GTD

- Evidence of metastases in brain, liver or gastrointestinal tract, or radiological opacities more than 2 cm on chest X-ray
- Histological evidence of choriocarcinoma
- Heavy vaginal bleeding or evidence of gastrointestinal or intraperitoneal haemorrhage
- Pulmonary, vulval or vaginal metastases unless hCG falling
- Rising hCG after evacuation
- Serum hCG = 20,000 IU/l more than 4 weeks after evacuation, because of the risk of uterine perforation
- Raised hCG 6 months after evacuation, even if still falling

Table 43.2 Factors increasing the risk of requiring chemotherapy following evacuation of an hydatidiform mole

Factor

- Uterine size greater than gestational age (Curry et al 1975)
- Pre-evacuation serum hCG above 100,000 IU/l (Berkowitz and Goldstein 1981)
- Oral contraceptives given before hCG falls to normal (Stone et al 1976)
- Bilateral cystic ovarian enlargement (Berkowitz and Goldstein 1981)

hCG, human chorionic gonadotrophin.

to include some of the WHO variables (Goldstein et al 1998). An international committee was then established, and recommended a new combined WHO/FIGO scoring system in 2000. This was internationally accepted in 2002, so that all centres managing this rare group of diseases can compare their results more easily (Kohorn 2002).

The authors currently use both the Charing Cross system and the new combined system as outlined in Tables 43.3 and 43.4. In both systems, each variable carries a score which, when added together for an individual patient, correlates with the risk of the tumour becoming resistant to single-agent therapy. It is this score, rather than the stage, that determines treatment; thus far, there appears to be excellent concordance for assigning patients to either low- or high-risk groups (see section on chemotherapy below). The most important prognostic variables carry the highest score and include:

- duration of the disease because drug resistance of GTTs varies inversely with time from the original antecedent pregnancy;
- serum hCG concentration which correlates with the volume of viable tumour in the body; and
- presence of liver or brain metastases.

Liver metastases correlate with a worse prognosis than brain metastases (Bower et al 1997), so patients with liver involvement score six points rather than four. Since the ABO blood groups contribute little to the scoring system and it is difficult to have complete data on both patients and relevant partners, this has been dropped from the system.

Chemotherapy

At Charing Cross Hospital, the prognostic scoring system in Table 43.3 has been used to subdivide the patients into three groups (low, medium and high risk) depending on their overall score. Formerly, each risk group corresponded with a separate treatment regimen and so there were three types of therapy (low, medium and high risk). Ten years ago, the medium-risk treatment was discontinued for three reasons:

Table 43.3 Scoring system for gestational trophoblastic tumours (Charing Cross Hospital)

Prognostic factor	Score			
	0	1	2	6
Age (years)	<39	>39	–	–
Antecedent pregnancy	Mole	Abortion or unknown	Term	–
Interval (end of antecedent pregnancy to chemotherapy in months)	<4	4–7	7–12	>12
hCG (IU/l)	10^3 – 10^4	< 10^3	10^4 – 10^5	> 10^5
Number of metastases	0	1–3	4–8	>8
Site of metastases	None, lung, vagina	Spleen, kidney	Gastrointestinal tract	Brain, liver
Largest tumour mass	–	3–5 cm	>5 cm	–
Prior chemotherapy	–	–	Single drug	Two drugs or more

hCG, human chorionic gonadotrophin.

The total score for a patient is obtained by adding the individual scores for each prognostic factor. Low risk, 0–8; high risk, ≥ 9 . Patients scoring 0–8 currently receive single-agent therapy with methotrexate and folinic acid, while patients scoring ≥ 9 receive combination drug therapy with EMA/CO (see Table 43.6).

Table 43.4 Scoring system for gestational trophoblastic tumours (World Health Organization/ International Federation of Gynaecology and Obstetrics)

Prognostic factor	Score			
	0	1	2	4
Age (years)	<40	≥40	–	–
Antecedent pregnancy	Mole	Abortion	Term	–
Interval (end of antecedent pregnancy to chemotherapy in months)	<4	4–6	7–13	>13
hCG (IU/l)	<10 ³	10 ³ –10 ⁴	10 ⁴ –10 ⁵	>10 ⁵
Number of metastases	0	1–4	5–8	>8
Site of metastases	Lung	Spleen, kidney	Gastrointestinal tract	Brain, liver
Largest tumour mass	–	3–5 cm	>5 cm	
Prior chemotherapy	–	–	Single drug	Two drugs or more

hCG, human chorionic gonadotrophin.
The total score for a patient is obtained by adding the individual scores for each prognostic factor. Low risk, 0–6; high risk, ≥7.

- the short- and long-term toxicity of this treatment is probably not significantly different from that of high-risk therapy;
- some patients that receive medium-risk treatment have developed drug resistance and subsequently require high-risk treatment; and
- approximately 30% of medium-risk patients can be cured on low-risk chemotherapy, which is less toxic than either medium- or high-risk chemotherapy (Rustin et al 1996). Moreover, there is no evidence that prior treatment failure with methotrexate is an adverse prognostic variable (Bower et al 1997, McNeish et al 2002).

Accordingly, patients who score between five and eight now receive low-risk chemotherapy, which was previously only given to those with a score = five. Patients scoring nine are given high-risk treatment. The details of both low- and high-risk treatment are discussed below. Patients are admitted for the first 3 weeks of either therapy, principally because the tumours are often highly vascular and may bleed vigorously in this early period of treatment.

Low-risk patients

Patients with low-risk disease have a 5-year survival rate of nearly 100% (Bower et al 1997). The regimen used since 1964 at Charing Cross Hospital and widely followed in other centres is shown in Table 43.5. This schedule is well tolerated with no alopecia, and since the folinic acid dose has been increased from 7.5 mg to 15 mg, the incidence of mucosal ulceration has reduced from 20% to just 2%. Methotrexate can induce serositis, resulting in pleuritic chest pain or abdominal pain. Myelosuppression is rare, but a full blood count should be obtained before each course of treatment. Liver and renal function should also be monitored regularly. All patients are advised to avoid sun exposure or use complete sun block for 1 year after chemotherapy because the drugs can induce photosensitivity.

Table 43.5 Chemotherapy regimen for low-risk patients

Methotrexate/folinic acid	
Methotrexate	50 mg by intramuscular injection repeated every 48 h for a total of four doses
Calcium folinate	15 mg orally 30 h after each injection of methotrexate (folinic acid)
Courses repeated every 2 weeks, i.e. days 1, 15, 29, etc.	

Approximately 33% of low-risk patients will need to change therapy: 31% because of drug resistance and 2% due to treatment toxicity (usually mucositis, occasionally severe pleuritic pain or drug-induced hepatitis) (McNeish et al 2002). However, in the authors' experience, all such patients are cured and the only deaths in this group of patients over the last 30 years were one from concurrent but not therapy-induced non-Hodgkin's lymphoma and one from hepatitis (Bagshawe et al 1989). Moreover, there is no evidence that methotrexate alone increases the risk of developing a second cancer (Rustin et al 1996).

High-risk patients

These patients are at high risk of developing drug resistance, and since 1979 have been treated with an intensive regimen consisting of etoposide, methotrexate and actinomycin D (EMA) alternating weekly with cyclophosphamide and vincristine, otherwise known as 'Oncovin' (CO; see Table 43.6). A recent meta-analysis has failed to demonstrate superiority of any other chemotherapy combination (Xue et al 2006). The EMA/CO regimen requires one overnight stay every 2 weeks and causes reversible alopecia. It is also myelosuppressive, but prolonged gaps in therapy, which may permit tumour regrowth, can usually be avoided by the following measures: continuing to treat unless the white cell count is less than $1.5 \times 10^9/l$ and/or platelets fall below $60 \times 10^9/l$.

Table 43.6 Chemotherapy regimen for high-risk patients

EMA		
Day 1	Etoposide	100 mg/m ² by IV infusion over 30 min
	Actinomycin D	0.5 mg IV bolus
	Methotrexate	300 mg/m ² by IV infusion over 12 h
Day 2	Etoposide	100 mg/m ² by IV infusion over 30 min
	Actinomycin D	0.5 mg IV bolus
	Folinic acid rescue (starting 24 h after commencing the methotrexate infusion)	15 mg IM or orally every 12 h for four doses
CO		
Day 8	Vincristine	1 mg/m ² IV bolus (max. 2 mg)
	Cyclophosphamide	600 mg/m ² IV infusion over 30 min

EMA, etoposide, methotrexate and actinomycin D; CO, cyclophosphamide and vincristine.
 EMA alternates with CO every week. To avoid extended intervals between courses caused by myelosuppression, it may occasionally be necessary to reduce the EMA by omitting the day 2 doses of etoposide and actinomycin D.

and/or mucosal ulceration develops. The introduction of granulocyte colony-stimulating factor in patients who have a low neutrophil count also helps to maintain treatment intensity and has reduced the number of neutropenic febrile episodes.

The cumulative 5-year survival of patients treated with this schedule is 86%, with no deaths from GTTs beyond 2 years after the initiation of chemotherapy (Bower et al 1997). While these results were good, the presence of liver or brain metastases correlated with only 30% or 70% long-term survival, respectively. Indeed, long-term survival in patients with both liver and brain metastases is only 10% (Newlands et al 2002). Interestingly, for patients with brain metastasis, if one excludes patients who were too sick to receive chemotherapy and died within a few days of admission, the survival rates appear to be the same as those for patients without brain involvement (Newlands et al 2002). The authors are currently undertaking a new analysis on patients with liver metastasis; of 38 patients treated more recently, the overall survival rate appears to be higher at just under 50% (Seckl et al, unpublished observations). This improvement in outcome may be because of changes in treatment. Other adverse prognostic variables include a longer interval from the antecedent pregnancy, and term delivery in the antecedent pregnancy (Powles et al 2007).

Early deaths accounted for a significant proportion of the overall mortality, with the causes being respiratory failure, cerebral metastases, hepatic failure and pulmonary embolism (Bower et al 1997). Importantly, these women did not have an HM, were not registered for follow-up and consequently presented with extensive disease. Clearly, it will be difficult to improve the survival of this particular subgroup. However, any woman of childbearing age presenting with

widespread malignancy should have an hCG measurement as very high levels of this hormone are highly suggestive of choriocarcinoma.

The long-term risk of chemotherapy-induced second tumours in patients treated for GTTs in the authors' centre has been reviewed previously (Rustin et al 1996), and is discussed below in the section on long-term complications of therapy.

Management of drug-resistant disease

GTN is one of a very small minority of malignant conditions where patients who progress on or after primary chemotherapy still have a good chance of cure [>90% overall 5-year survival in a recent case series (Powles et al 2007)].

Low-risk disease

Frequent (twice-weekly) measurement of serum hCG is a simple way to detect drug resistance at an early stage as the hormone levels will stop falling and may start to rise long before there are other clinical changes. Decisions to alter treatment are not made on the basis of a single hCG result but on a progressive trend over two to three values. For patients receiving methotrexate for low-risk disease, if the hCG is below 100 IU/l when drug resistance occurs, the disease can often be cured simply by substituting actinomycin D (0.5 mg IV total dose daily for 5 days every 2 weeks) (McNeish et al 2002). This drug is more toxic than methotrexate, inducing some hair thinning (occasional complete alopecia), myelosuppression and more oral ulceration. However, it is preferable to EMA/CO. Indeed, more recently, in order to reduce the number of patients proceeding directly to this more toxic regimen, the authors have raised the hCG level for switching from methotrexate to actinomycin D therapy to less than 300 IU/l. The cure rate, even in those rare cases that need three or more lines of treatment, remains nearly 100% (Powles et al 2007).

Low-risk patients failing methotrexate whose serum hCG level is above 300 IU/l are treated with EMA/CO.

High-risk disease

Seventy per cent of patients who have failed EMA/CO for high-risk disease can still be salvaged by further chemotherapy and/or surgery (Bower et al 1997). Indeed, the combination of surgical removal of the main site of drug resistance (usually uterus, lung or brain) together with chemotherapy is particularly effective. Preoperative investigations include those outlined above. If all of these investigations are negative, hysterectomy should be considered. Following surgery or when surgery is not appropriate, the authors use the cisplatin-containing regimen, EP (etoposide 150 mg/m² and cisplatin 75 mg/m² with hydration) alternating weekly with EMA (omitting day 2 except the folinic acid). Although this regimen is very toxic, the outcome has been impressive with survival rates in excess of 80% (Newlands et al 2000).

Other options that can be considered include use of some of the newer anticancer agents such as the taxanes, topotecan, gemcitabine and temozolomide. Several cases of drug-resistant GTTs that have responded to paclitaxel-based single-agent or combination therapy have been

reported (Jones et al 1996, Termrungruanglert et al 1996, Osborne et al 2004, Shorbagi et al 2005). An alternating doublet of paclitaxel/cisplatin and paclitaxel/etoposide (TP/TE) has been found to be well tolerated and effective in patients with relapsed and/or refractory GTN (Wang et al 2008). Overall survival ranged from 44% for patients who failed previous cisplatin-based chemotherapy to 75% for those receiving TP/TE as a result of discontinuing prior chemotherapies due to toxicities.

Another approach in patients with refractory disease involves high-dose chemotherapy with autologous bone marrow or peripheral stem cell transplantation. Patient selection here is important in determining outcome as it has been shown for refractory germ cell tumours that patients with drug-sensitive disease stay in remission (Beyer et al 1996, Lyttelton et al 1998). In the largest series of high-dose chemotherapy for refractory GTT, five out of 11 patients showed a temporary partial or complete response, although all but one patient progressed eventually (El-Helw et al 2005). Since the time of writing, the authors have treated several more cases and now appear to have two long-term survivors. Therefore, high-dose chemotherapy with autologous stem cell support for GTN remains investigational. Further studies are needed to better define the role of high-dose chemotherapy, in particular in patients with high-risk GTN who fail their first salvage treatment for recurrent disease.

Management of acute disease-induced complications

Haemorrhage

Heavy vaginal or intraperitoneal bleeding is the most frequent immediate threat to life in patients with GTTs. The bleeding mostly settles with bed rest and appropriate chemotherapy. However, occasionally, the bleeding can be torrential, requiring massive transfusion. In this situation, if the bleeding is coming from the uterus, it may be necessary to consider a uterine pack or emergency embolization of the tumour vasculature. Fortunately, hysterectomy is rarely required. If the bleeding is intraperitoneal and does not settle with transfusion and chemotherapy, laparotomy may be required. Indeed, patients occasionally present this way.

Respiratory failure

Occasionally patients present with respiratory failure due to multiple pulmonary metastases or, more rarely, as a result of massive tumour embolism to the pulmonary circulation (Savage et al 1998). However, in the authors' experience, these patients can be cured with appropriate management. Oxygen support may be required, including masked continuous positive airway pressure ventilation, but mechanical ventilation is usually contraindicated as it results in trauma to the tumour vasculature, leading to massive intrapulmonary haemorrhage and death.

Management of cerebral metastases

The presence of neurological symptoms and signs may alert the clinician to the presence of brain metastases. However, some high-risk patients do not have either overt pulmonary

or CNS disease at presentation, but subsequently develop cerebral metastases which are then drug resistant. Consequently, careful investigation of patients at risk of developing brain metastases is warranted so that appropriate CNS-penetrating chemotherapy is given rather than the standard low- or high-risk treatments.

Prophylaxis against possible CNS disease, i.e. in the presence of a normal MRI brain, is given to patients from all risk categories with lung metastases and all high-risk patients regardless of the absence or presence of lung deposits. The prophylaxis consists of 12.5 mg methotrexate administered intrathecally, followed 24 h later by 15 mg folinic acid orally. This is given with every course of low-risk therapy, or with each CO in the high-risk therapy for three doses. Since the introduction of this policy, the development of brain metastases without evidence of drug resistance elsewhere has been much less frequent (Athanassiou et al 1983).

Overt CNS disease requires careful management as therapy can induce haemorrhage into the tumour, leading to a rise in intracranial pressure and subsequent loss of life (Athanassiou et al 1983). Early resection of solitary brain deposits in patients with serious neurological signs can sometimes be life-saving (Ishizuka 1983, Song and Wu 1988, Rustin et al 1989). Cerebral oedema can be reduced with high-dose corticosteroids, so patients are given 24 mg dexamethasone in divided doses before starting chemotherapy. The EMA/CO regimen is modified by increasing the dose of methotrexate to 1 g/m², given as a 24-h infusion on day 1. The folinic acid rescue is increased to 30 mg given 8-hourly intravenously for 3 days, commencing 32 h after the start of methotrexate infusion. Provided that there is no evidence of raised intracranial pressure, 12.5 mg methotrexate is given intrathecally with each CO until the serum hCG level is normal. Modified EMA/CO is then continued for a further 6–8 weeks. Overall, long-term remission can be achieved in approximately 80% of patients with cerebral metastases (Newlands et al 2002). Patients who survive the first 3 weeks of such treatment have a good prognosis, with an 86–89% chance of cure (Athanassiou et al 1983, Rustin et al 1989, Newlands et al 2002).

Patients who develop cerebral tumours during chemotherapy have a poor prognosis because their disease is almost certainly drug resistant. Nevertheless, a combination of immediate surgery to remove the deposit(s) and modified chemotherapy designed to provide better CNS penetration can be curative in this situation (Athanassiou et al 1983, Rustin et al 1989). Radiotherapy has been advocated as an alternative therapeutic approach. However, it has not been shown to eradicate tumour in its own right, and in combination with chemotherapy has produced less effective results than chemotherapy alone. Nevertheless, stereotactic radiotherapy probably has a role in the treatment of isolated deep lesions that cannot be removed surgically, especially if still present at the end of chemotherapy.

Management of placental-site trophoblastic tumours

PSTTs differ from the other forms of GTD in that they grow slowly, metastasize late and produce little hCG. This is because hCG is produced in high levels by syncytiotrophoblasts, which are not present in PSTTs, and only in low

levels by intermediate trophoblasts. However, in the authors' experience of over 60 cases, it is still an accurate biomarker.

PSTTs are relatively resistant to combination chemotherapy regimens, and therefore hysterectomy with pelvic lymph node clearance and ovarian preservation remains the treatment of choice provided that the disease is localized to the uterus (stage I). In these patients, 10-year survival is 90% and there is no clear benefit from pre- and/or postoperative chemotherapy (Schmid et al 2008). However, for patients with disease in the resection margin or lymphovascular invasion, the authors routinely offer adjuvant EP/EMA and, more recently, TE/TP chemotherapy for 8 weeks until more data are available.

When disease has spread beyond the uterus, patients can respond to and be cured by chemotherapy (EP/EMA) either alone or in combination with surgery (Newlands et al 1998b). Ten-year survival rates are 52% for locoregional (stage II) disease and 49% for metastatic (stage III/IV) disease. In the largest series of 62 patients, 9% had refractory disease and died of PSTTs (Schmid et al 2008).

Nineteen per cent of patients treated for PSTTs experience disease recurrence, all within the first 5 years (Schmid et al 2008). In this group, the outlook is poor with a minority achieving long-term survival. Radiotherapy does not appear to add much to the management, and it is unlikely that a high dose will be curative, although the latter should be considered in chemoresponsive patients who have failed first-line therapies. The most important prognostic variable is the interval from the antecedent pregnancy (Newlands et al 2000). A cut-off of 4 years discriminates patients with a positive predictive value of 100% and a negative predictive value of 98% (Schmid et al 2008). PSTTs are so rare that it is unlikely that their treatment will ever be fully optimized.

The major question in the management of PSTTs, which frequently affect women of childbearing age, is whether fertility-sparing surgery is safe in a minority of cases with good prognostic factors and disease localized to a single uterine site. There have been five reported cases of attempted fertility-sparing surgery using a variety of surgical techniques with and without postoperative chemotherapy, with mixed results. One case had a successful pregnancy, two cases achieved long-term remission but no term pregnancy, and two cases went on to need a hysterectomy for relapsed disease (Leiserowitz and Webb 1996, Tsuji et al 2002, Machtinger et al 2005, Pfeffer et al 2007). In one case at relapse, it was found post hysterectomy that disease that appeared localized to a single uterine site on imaging, including ¹⁸FDG-PET, was in fact multifocal throughout the uterus. Any attempts at fertility-sparing surgery should be undertaken cautiously with preoperative counselling of the patient and close postoperative follow-up.

Patient Follow-Up after Chemotherapy

On completion of their chemotherapy, patients are followed-up regularly with hCG estimations (Table 43.7) to confirm that their disease is in remission. The risk of relapse is approximately 3% and is most likely in the first year of follow-up. However, the authors currently continue follow-up for life, until a full set of data are available to more accurately indicate when it may be safe to stop.

Table 43.7 Follow-up of patients with gestational trophoblastic tumours who have been treated with chemotherapy

		Low-/high-risk postchemotherapy patients, hCG concentration sampling	
Year 1	Weeks 1–6 after chemotherapy Months 2–6 Months 7–12	Urine	Blood
		Weekly	Weekly
		2-weekly	2-weekly
		2-weekly	–
Year 2		4-weekly	–
Year 3		8-weekly	–
Year 4		3-monthly	–
Year 5		4-monthly	–
After Year 5		6-monthly	–
hCG, human chorionic gonadotrophin.			

Timing of Pregnancy after Treatment

Patients are advised not to become pregnant until 12 months after completing their chemotherapy. This minimizes the potential teratogenicity of treatment and avoids confusion between a new pregnancy and relapsed disease as the cause of rising hCG. Despite this advice, 230 women on follow-up at the authors' centre between 1973 and 1997 have become pregnant during the first year. Fortunately, this does not appear to be associated with an increased risk of relapse or fetal morbidity, and there were no maternal deaths. Indeed, 72% of women continued their pregnancy to term (Blagden et al 2002). Consequently, although the authors continue to advise women to avoid pregnancy for 1 year after completing chemotherapy, those that become pregnant can be reassured of a likely favourable outcome. When a patient becomes pregnant, it is important to confirm by US and other appropriate means that the pregnancy is normal. Follow-up is then discontinued until 3 weeks after the end of pregnancy, when the hCG due to the pregnancy should have returned to normal.

Patients who do not require chemotherapy following evacuation of their first mole, although not on life-long follow-up, should have their hCG levels measured 6 and 10 weeks after any subsequent pregnancy. This is because they are at increased risk compared with the general population of a further molar pregnancy (Sebire et al 2003). In addition, with a subsequent pregnancy, there is a small risk of reactivation of 'dormant' residual molar tissue, even if the pregnancy itself is normal.

Contraceptive Advice

Patients using oral contraceptives before the hCG level is normal following evacuation of an HM have an increased risk of developing persistent GTD (Stone et al 1976). Other

centres have not been able to reproduce this finding, so this area is controversial. Nevertheless, the authors' data set is very large; for this reason, patients in the UK are advised to avoid the oral contraceptive pill until the hCG level has returned to normal after removal of an HM. Patients who have had chemotherapy for their GTT are advised not to use the oral contraceptive pill until their hCG level is normal and chemotherapy is completed.

Long-Term Complications of Therapy

Most patients, including those who have received intensive chemotherapy, return to normal activity within a few months, and the majority of the side-effects are reversible, including alopecia. Late sequelae from chemotherapy have been remarkably rare. In 15,279 patient-years of follow-up, there was no significant increase in the incidence of second tumours (Rustin et al 1996) following methotrexate therapy. In contrast, 26 patients receiving combination chemotherapy for GTTs developed another cancer when the expected rate was only 16.45; a significant difference (Rustin et al 1996).

Fertility is an important issue in the management of patients with GTTs. Although combination chemotherapy induces the menopause 3 years earlier than expected (Bower et al 1998), fertility does not otherwise appear to be affected. In 392 patients receiving single-agent methotrexate, 327 (83.4%) had successful live births, whilst in the 336 patients receiving multi-agent chemotherapy, including EMA/CO, 280 (83.3%) also succeeded in having normal

pregnancies (Woolas et al 1998). There is no increase in the incidence of congenital malformations compared with the general population (Rustin et al 1984, Woolas et al 1998).

Prognosis

All patients in the low-risk groups can be expected to be cured of their GTTs (Bagshawe and Begent 1983, Newlands et al 1986). For high-risk patients, survival has improved progressively and is currently 86% (Bower et al 1997). The diagnosis of choriocarcinoma is often not suspected until the disease is advanced. As a result, some deaths occur before chemotherapy has a chance to be effective. The number of such patients can be diminished by a greater awareness of the possibility that multiple metastases in a woman of child-bearing age may be due to choriocarcinoma. The simple measurement of the hCG level in such individuals is a very strong indicator of choriocarcinoma, and could help to hasten referrals for life-saving chemotherapy.

Conclusion

In the past, many women have died from GTD. However, during the last 50 years, much has been learnt about the biology, pathology and natural history of this group of disorders. Furthermore, accurate diagnostic and monitoring methods have been developed, together with effective treatment regimens. As a result, the management of GTD today represents one of the modern success stories in oncology, with few women dying from trophoblastic tumours.

KEY POINTS

1. CM and PM are the most common forms of GTD.
2. First-trimester bleeding is the most common presentation.
3. Prostanoids are contraindicated prior to evacuation, even in nulliparous women.
4. Second evacuation should be discussed with a GTD centre, and more than two evacuations is contraindicated.
5. All confirmed cases should be registered for hCG follow-up.
6. If in doubt, get histology reviewed by GTD centre.
7. RIA remains the gold standard for hCG testing in GTD.
8. Sixteen per cent of CM and 0.5% of PM will require chemotherapy and all can expect to be cured.
9. Deaths from GTTs are usually due to late recognition of a post-term choriocarcinoma or from metastatic PSTTs which are less chemosensitive.
10. Chemotherapy does not affect fertility significantly, but EMA/CO increases the risk of second tumours.

PHYSIOLOGICAL OVARIAN CYSTS	668	MANAGEMENT	671
CLINICAL PRESENTATION OF SYMPTOMATIC OVARIAN CYSTS	668	PATHOLOGY	672
DIFFERENTIAL DIAGNOSIS	669	KEY POINTS	677

Introduction

Ovarian cysts are common, frequently asymptomatic and often resolve spontaneously. They are the fourth most prevalent gynaecological cause of hospital admission. By 65 years of age, 4% of all women in England and Wales will have been admitted to hospital for this reason. Ovarian cysts are found either during the course of investigation of abdominal pain or as a result of imaging for other reasons. It is important to distinguish between ovarian cysts that will require assessment and management and those that will resolve spontaneously. In addition, reliable prediction of their benign or malignant nature would be beneficial in order to arrange appropriate referral and management, as per Improving Outcome Guidance (NHS Executive 1999).

In order to fully understand the nature of an ovarian cyst, one must understand the natural changes that occur in the ovary during the normal menstrual cycle. In the normal menstrual cycle, the ovary responds to an increased level of follicle-stimulating hormone by recruitment of eight to 10 follicles. By day 8, under the influence of an increased level of luteinizing hormone (LH), one follicle becomes the lead follicle and the rest regress. This lead follicle grows to approximately 16–20 mm and ovulation occurs 36 h after the LH surge. Thereafter, the cyst persists as a lipid-filled corpus luteum, producing the progesterone required to mature and maintain the endometrium for possible implantation of a fertilized ovum.

Physiological Ovarian Cysts

As pelvic ultrasound, particularly transvaginal scanning, is now used more frequently, physiological cysts are detected more often. The corpus luteum may persist and continue to secrete progesterone beyond its natural lifespan, and thus

cause some menstrual irregularity, or haemorrhage may occur into the cyst at or just after ovulation. Most good radiologists will recognize the features of a follicle, corpus luteum or haemorrhagic cyst and will report these as such. Most simple cysts will resolve spontaneously over a period of 6 months (Zanetta et al 1996, Saasaki et al 1999). Occasionally, they can persist for longer or grow in size to become a clinical problem. Physiological cysts should simply be regarded as large versions of the cysts which form in the ovary during the normal cycle.

Failure of development of the lead follicle results in anovulation and is a classical finding in polycystic ovary syndrome (PCOS). PCOS is predominantly an endocrine abnormality, and polycystic ovaries do not cause abdominal pain (see Chapter 18, Polycystic ovary syndrome, for more information).

Clinical Presentation of Symptomatic Ovarian Cysts

Benign ovarian cysts present as follows:

- acute and chronic pain;
- abdominal swelling, bloating and pressure effects; and
- menstrual disturbances and hormonal effects.

Pain

Acute-onset pain

For a woman to present with acute-onset abdominal pain in the presence of an ovarian cyst suggests a cyst accident such as torsion, rupture or haemorrhage. Torsion usually gives rise to an acute-onset sharp, constant pain caused by ischaemia of the cyst. Areas may subsequently become infarcted if there is delay in treatment, and pyrexia may develop. Haemorrhage may occur into the cyst and cause pain as the capsule

is stretched. Intraperitoneal bleeding mimicking ectopic pregnancy may result from rupture of the cyst, which is most often a ruptured, bleeding corpus luteum.

If the patient is haemodynamically unstable at the time of presentation, resuscitation and stabilization are priorities. At a minimum, a full blood count, cross-match and urinary human chorionic gonadotrophin (hCG) should be performed. If the urinary hCG is positive, a serum quantitative hCG would help in the diagnostic process. If it is possible to obtain emergency ultrasound imaging, this may be beneficial but surgery should not be delayed whilst waiting for investigations which would not necessarily affect the management.

Chronic pain

Pelvic inflammatory disease may give rise to a mass of adherent bowel, hydrosalpinx or pyosalpinx. In such circumstances, the pain will be gradual in onset rather than acute. It is often difficult to distinguish between a hydrosalpinx and an ovarian mass on ultrasound; if there is a diagnostic dilemma, laparoscopy should be considered.

Abdominal swelling, bloating and pressure effects

Patients seldom note abdominal swelling until the tumour is very large. A benign mucinous cyst may occasionally fill the entire abdominal cavity. Bloating is a common symptom which can be associated with ovarian tumours but most often is not. Gastrointestinal or urinary symptoms may result from pressure effects. In extreme cases, oedema of the legs, varicose veins and haemorrhoids may result. Sometimes, uterine prolapse is the presenting complaint in a woman with an ovarian cyst.

An attempt to assess symptoms qualitatively and quantitatively in order to distinguish women who may have an ovarian cyst from those unlikely to have a cyst suggests that recent-onset, severe and persistent symptoms should warrant further investigation (Bankhead et al 2008).

Hormonal effects

Occasionally, the patient will complain of menstrual disturbances but this may be coincidence rather than due to the tumour. Rarely, ovarian tumours present with oestrogen effects such as precocious puberty, menorrhagia, glandular hyperplasia, breast enlargement and postmenopausal bleeding. Secretion of androgens may cause hirsutism and acne initially, progressing to frank virilism with deepening of the voice and clitoral hypertrophy. Very rarely indeed, thyrotoxicosis may occur. Some of these tumours are malignant, but are mentioned here because of their ability to produce hormones in some cases. The hormonal effects and histology are discussed later.

Predominantly oestrogen-secreting tumours

- Granulosa cell tumours
- Thecoma
- Sertoli cell tumours (sex cord tumour with annular tubules)

Predominantly androgen-secreting tumours

- Sertoli-Leydig tumours (androblastomas)
- Adrenal-like tumours
- Gonadoblastoma

Differential Diagnosis

The differential diagnosis of benign ovarian tumours is broad, reflecting the wide range of presenting symptoms.

Pain

- Ectopic pregnancy
- Spontaneous abortion
- Pelvic inflammatory disease
- Appendicitis
- Meckel's diverticulum
- Diverticulitis

Abdominal swelling

- Pregnant uterus
- Fibroid uterus
- Full bladder
- Distended bowel
- Ovarian malignancy
- Colorectal carcinoma

Pressure effects

- Urinary tract infection
- Constipation

Hormonal effects

- All other causes of menstrual irregularities, precocious puberty and postmenopausal bleeding

A full bladder should be considered in the differential diagnosis of any pelvic mass. In premenopausal women, a gravid uterus must always be considered. Fibroids can be impossible to distinguish from ovarian tumours. Rarely, a fimbrial cyst may grow sufficiently to cause anxiety.

Investigation

The investigations required will depend upon the circumstances of the presentation. The patient presenting with acute symptoms will usually require emergency surgery, whereas the asymptomatic patient or the woman with chronic problems may benefit from more detailed preliminary assessment.

Gynaecological history

Details of the presenting symptoms and a full gynaecological history should be obtained, with particular reference to the date of the last menstrual period, the regularity of the menstrual cycle, any previous pregnancies, contraception, medication and family history (particularly of ovarian or breast cancer).

General history and examination

Indigestion or dysphagia combined with profound weight loss might indicate a primary gastric cancer metastasizing to the pelvis. Similarly, a history of altered bowel habit or rectal bleeding should be sought as evidence of diverticulitis or large bowel carcinoma. Ovarian carcinoma may also present with these features.

If the patient has presented as an emergency, evidence of hypovolaemia should be sought. Hypotension is a relatively late sign of blood loss, as the blood pressure will be maintained for some time by peripheral and central venous vasoconstriction. When decompensation of this mechanism occurs, it often does so very rapidly. It is vital to recognize the early signs (i.e. tachycardia and cold peripheries). In these circumstances, it is not appropriate to delay surgery pending further investigations, and laparotomy is the correct course of action.

If a cyst is found, the chest should be examined for signs of a pleural effusion. Peripheral oedema can indicate both pressure symptoms and hypoproteinaemia. It is also important to rule out other sites of tumours that are known to metastasize to the ovary, such as the breasts; thus, a full clinical examination is indicated.

Abdominal examination

The abdomen should be inspected for signs of distension by fluid or by the tumour itself. Dilated veins may be seen on the lower abdomen. Gentle palpation will reveal areas of tenderness and peritonism. The best way of detecting a mass that arises from the pelvis is to palpate gently with the left hand, starting in the upper abdomen and working caudally. This is the reverse of the process taught to every medical student for feeling the liver edge. Use of the right hand alone is the most common reason for failing to detect pelvic-abdominal masses.

Shifting dullness is probably the easiest way of demonstrating ascites, but it remains a very insensitive technique. If present, examination of the chest is required to determine if a pleural effusion is also present. It is always worth listening for bowel sounds in any patient with an acute abdomen. Their complete absence in the presence of peritonism is an ominous sign.

Bimanual examination

This is an essential component of the assessment because, even in expert hands, ultrasound examination is not infallible. By palpating the mass between both the vaginal and abdominal hands, its mobility, texture and consistency, the presence of nodules in the pouch of Douglas and the degree of tenderness can be determined. While it is impossible to make a firm diagnosis with bimanual examination, a hard, irregular, fixed mass is likely to be invasive.

Investigations

As a minimum, urine should be tested for the presence of infection and pregnancy. Blood should be obtained for a full blood count, blood grouping and cross-match if the patient is haemodynamically unstable. If the clinical

signs suggest the possibility of upper gastrointestinal pathology, liver function tests and serum amylase should be performed.

Serum tumour markers

CA125 is well established in the investigation of ovarian cysts. It is a tumour marker for peritoneal disease/irritation, and whilst not specific for ovarian cancer, a level above 30 u/ml is abnormal. Benign conditions that increase the level of CA125 are endometriosis and pelvic inflammatory disease. In an acute cyst accident, it may also be raised; however, levels above 250 u/ml are almost always associated with malignant disease. The level of CA125 is increased in 80% of ovarian cancers. Other tumour markers may be useful in certain circumstances. If the tumour has features suggestive of a teratoma (dermoid), alpha-fetoprotein and hCG help to determine its malignant potential. Carcinoembryonic antigen, C15.3 and C19.9 are indicated when there is a possibility of pathology other than primary ovarian. Occasionally, the ovary may contain a rare tumour called a 'granulosa cell tumour'; in this case, serum inhibin levels are useful in tracking the course of disease.

Ultrasound

The techniques of transabdominal and transvaginal ultrasound are discussed in detail in Chapter 6. Ultrasound is the single most important investigation and can demonstrate the presence of an ovarian mass with 81% sensitivity and 75% specificity. Most ovarian masses are cystic, whilst the presence of solid areas makes a malignancy more likely. Reporting of an ultrasound finding of an ovarian cyst has been standardized in order to allow for the allocation of a scoring system to assist in the preoperative assessment of the risk of any ovarian cyst being malignant. The ultrasound is awarded a U score of 0 if no cyst is present, 1 if only one characteristic is found, and 3 if two or more characteristics are found:

- Multilocular
- Evidence of solid areas
- Evidence of metastases
- Presence of ascites
- Bilateral lesions

Computed tomography (CT) scanning has no significant advantages over ultrasound in cyst assessment, but can be useful in the presence of obvious extrapelvic disease to assess tumour bulk prior to chemotherapy. Magnetic resonance imaging (MRI) has a marginal advantage over CT in determining if a cyst is more likely to be benign or malignant, but both have no benefit over good transvaginal ultrasound and should not be used routinely. Initial studies using colour flow Doppler were promising but, once again, its use has not been proven to improve cyst assessment.

Risk of malignancy index

There is good evidence that primary surgery undertaken by a gynaecological oncologist improves survival in ovarian cancer by allowing for adequate staging and optimal debulking. It is not practical for all cysts to be managed by gynaecological

colological oncologists; thus, in order to triage cysts for the appropriate surgeon, the Royal College of Obstetricians and Gynaecologists (RCOG) recommend use of the risk of malignancy index (RMI). In order to calculate the RMI, the menopausal status is also taken into account, with premenopausal being awarded a score of 1 and postmenopausal being awarded a score of 3. This simple formula is used:

$$\text{RMI} = \text{CA125} \times \text{U score} \times \text{Menopausal status}$$

A score below 25 can be managed by any gynaecologist, a score of 25–250 should be managed by a cancer unit lead, and a score above 250 should be referred to a cancer centre. This assessment allows for 70% of ovarian cancers to be managed in a cancer centre. The specificity is 90%. The cysts most likely to result in confusion regarding their benign or malignant nature are endometriomas. The clinical history and examination may better inform the clinician but, as a general principle, a significantly raised CA125 (>300 u/ml) is almost always associated with malignant disease.

The Scottish Collegiate also uses an RMI scoring system but gives different weightings to the ultrasound findings and menopausal status. If there are two or more abnormal ultrasound features, they award a U score of 4, whilst a postmenopausal status also has a score of 4. In addition, referral to a cancer centre is recommended when the RMI score is above 200. These adaptations increase the sensitivity of the RMI for prediction of malignant disease from 70% to 80%, and increase the specificity from 89% to 92%. Many centres in the UK also apply this RMI.

Ultrasound-guided diagnostic ovarian cyst aspiration

This investigation has been introduced gradually into gynaecological practice without the benefit of appropriate trials to indicate its potential efficacy. Unfortunately, this technique has a false-negative rate of up to 71% and a false-positive rate of 2% for the cytological diagnosis of malignancy (Diernaes et al 1987). The degree of risk of dissemination of malignant cells along the needle track or into the peritoneal cavity is not established. Most simple cysts will resolve, and most complex cysts require definitive management. Thus, due to its poor prognostic value and the potential for upstaging an early malignancy, cyst aspiration is not recommended for the assessment or management of ovarian cysts.

Management

The management will depend upon the severity of the symptoms, the size and ultrasound characteristics of the cyst, the CA125 results and the age of the patient, and therefore the risk of malignancy and her desire for further children.

The asymptomatic patient

This includes women whose cysts were diagnosed incidentally during investigation of another problem or during

investigation of lower abdominal symptoms that may or may not be related to the cyst.

Simple cysts less than 8 cm in diameter with normal CA125 levels

A normal follicular cyst up to 3 cm in diameter requires no further investigation. A simple cyst which is unilocular, echo-free without solid parts or papillary formations less than 8 cm in diameter with a normal CA125 level should have a repeat ultrasound in 3–6 months. If the cyst persists or grows, laparoscopic removal is advised. Premenopausal women under 40 years of age are more likely to want the option of further children and less likely to have a malignant epithelial tumour. In a study by Ekerhovd et al (2001), only three (0.73%) of 413 premenopausal women who underwent surgery for simple echo-free cysts without solid parts or papillary formations had borderline ($n = 2$) or malignant ($n = 1$) tumours.

The use of a combined oral contraceptive is unlikely to accelerate the resolution of a functional cyst (Steinkampf and Hammond 1990). Hormonal treatment of endometriosis does not usually benefit an endometrioma, the mainstay management of which is surgical.

The older woman

Women over 50 years of age are far more likely to have a malignancy and have less to gain from the conservative management of a pelvic mass. However, the capacity of the postmenopausal ovary to generate benign cysts is greater than previously thought, occurring in up to 17% of asymptomatic women (Levine et al 1992). Over 50% of simple cysts will resolve spontaneously and almost 30% will remain static (Levine et al 1992, Bailey et al 1998, Saasaki et al 1999).

Considerable efforts have been made to safely avoid unnecessary surgery in this older age group. However, one group found malignant tumours in 8.9% of 112 postmenopausal women with monolocular simple cysts studied between 1987 and 1993 with transvaginal ultrasound (Osmers et al 1998). They did not find internal echoes helpful in identifying malignancies. They found malignancies in 4.6% of cysts less than 40 mm in diameter, 10.8% of cysts 40–69 mm in diameter, and 18.2% of cysts more than 69 mm in diameter. Their view was that only cysts less than 3 cm in diameter could be managed conservatively. The results of other studies are more reassuring. In particular, a more recent study running from 1992 to 1997 found that only 1.6% of 247 echo-free cysts in postmenopausal women were malignant and that all of these were more than 7.9 cm in diameter (Ekerhovd et al 2001). It was only cysts with small solid areas or papillary formations on the internal side of the cyst wall or echogenic cyst content that carried a 10% risk of malignancy in the 130 cysts studied. Of the nine invasive cancers detected in this group, five were in cysts less than 8 cm in diameter.

This suggests that simple, echo-free, unilateral cysts without solid parts or papillary formations and less than 8 cm in diameter are very likely to be benign, and may safely be managed conservatively with 3–6-monthly ultrasound and CA125 estimation (Goldstein 1993, Ekerhovd et al 2001).

All other cysts

Echo-free ovarian cysts more than 7.9 cm in diameter are unlikely to be physiological or to resolve spontaneously, and will be malignant in approximately 5% of premenopausal women and approximately 15% of postmenopausal women (Ekerhovd et al 2001). These are probably better removed or, at the very least, rescanned 3 months later if the woman is unwilling to undergo surgery.

If the cyst is not echo-free, unilocular or unilateral, or if the CA125 level is raised, surgical removal must be advised to all postmenopausal women regardless of the size of the lesion. In premenopausal women, a corpus luteum or an endometrioma will have a complex appearance on ultrasound and the CA125 level is often slightly raised. When these are suspected, a repeat scan in 3 months is reasonable, with surgery advised if the tumour persists. Otherwise, surgical removal should be advised.

The patient with symptoms

If the patient presents with severe, acute pain or signs of intraperitoneal bleeding, an emergency laparoscopy or laparotomy will be required. More chronic symptoms of pain or pressure may justify pelvic ultrasound if no mass can be felt.

The pregnant patient

An ovarian cyst in a pregnant woman may undergo torsion or may bleed. There is said to be increased incidence of these complications in pregnancy, although the evidence for this is poor. Very occasionally, it can prevent the presenting fetal part from engaging. An ovarian cyst is usually discovered incidentally at the antenatal clinic or on ultrasound. These are usually physiological and resolve by the time of the midtrimester scan.

A recent RCOG publication in *The Obstetrician and Gynaecologist* (2006) has clarified the position somewhat:

- If the cyst is symptomatic, remove it.
- If the cyst is less than 5 cm in diameter and simple, leave it alone.
- If the cyst is simple and more than 5 cm in diameter, or complex of any size, repeat scan in 4 weeks.
- If the cyst is more than 5 cm in diameter and complex in nature, arrange an MRI and MDT discussion:
 - If thought to be benign, remove post natally.
 - If thought to be malignant (7–11%), remove in the midtrimester.

The pregnant woman with an ovarian cyst is a special case because of the dangers of surgery to the fetus. These have probably been exaggerated in the past and no urgent operation should be postponed solely because of a pregnancy. Thus, if the patient presents with acute pain due to torsion or haemorrhage into an ovarian tumour, or if appendicitis is a possibility, the correct course is to undertake a laparotomy regardless of the stage of the pregnancy. The likelihood of labour ensuing is small; however, the operation should be covered by tocolytic drugs and performed in a centre with intensive neonatal care when possible.

The tumour marker CA125 is not useful in pregnant women, since elevated levels occur frequently as an apparent physiological change.

Cysts found by chance at caesarean section can also have a variety of management options. In summary:

- If the cyst is simple and less than 5 cm in diameter, leave it alone.
- If the cyst is complex or more than 5 cm in diameter, consider the following options:
 - Perform an ovarian cystectomy and open cyst. If any atypical feature (inclusions), remove ovary. Counsel patient of a 10% chance of a second operation if cystectomy only performed.
 - Perform oophorectomy and staging.

If there is a high clinical suspicion of malignancy, advice from an appropriately trained consultant colleague should be sought.

Pathology (Box 44.1)

Physiological ovarian cysts

These are included here because they can present as tumours when increased in size. However, most are asymptomatic, being found incidentally as a result of pelvic examination or ultrasound scanning. Although they may occur in any premenopausal woman, they are most common in young women. They are an occasional complication of ovulation induction, when they are commonly multiple. They may

also occur in premature female infants and in women with trophoblastic disease.

Simple follicular cyst

Lined by granulosa cells, a simple follicular cyst is the most common type of benign ovarian tumour and is most often found incidentally in women of reproductive age, particularly during the early years after the menarche. It results from the non-rupture of a dominant follicle, or the failure of normal atresia in a non-dominant follicle which is thought to result from continuous hormone stimulation of a developing cycle without the midcycle surge of LH that normally triggers ovulation. Follicular cysts may be associated with menstrual irregularities. They may rupture with the consequent clinical syndrome of acute abdominal presentation. Occasionally, oestrogen production may persist, leading to menstrual disturbances and endometrial hyperplasia.

Histologically, follicular cysts show a lining of variably luteinized granulosa cells.

Corpus luteum cyst

Sometimes, corpora lutea undergo central cystification, often associated with haemorrhage into their lumen. Not uncommonly, these will present as an acute haemorrhagic abdominal episode. The degree of cystic dilatation exceeding 2 or 3 cm (according to different authors) justifies the designation of 'corpus luteum cyst'.

Macroscopic identification is straightforward due to the intense yellowish colour resulting from mature luteinized theca cells (Figure 44.1).

Massive oedema

Massive oedema is not a physiological cyst but presents as a tumour. It occurs in young patients (average 21 years of age) presenting with abdominal pain and swelling. Presentation is largely unilateral, and torsion of the involved ovary is seen in half of cases.

Macroscopically, the size varies greatly from 5 to 35 cm in diameter. The external surface is smooth and the cut section surface typically exudes watery fluid. Microscopically, the stromal oedema is more intense towards the central parenchyma, sparing the fibrous cortex.

Ninety per cent of all ovarian tumours are benign, although this varies with age, and they can arise from any tissue in the ovary. Approximately one in eight ovarian tumours in patients under 45 years of age is malignant; by contrast, the proportion is one in three in older women (Scully et al 2004). Most benign ovarian tumours are cystic, and the finding of solid elements makes malignancy more likely. However, fibromata, thecomata, dermoids and some transitional cell tumours are totally benign despite being partly or predominantly solid.

Pathological ovarian cysts

The diagnosis of ovarian tumours ultimately depends upon histological examination.

Benign germ cell tumours

Germ cell tumours account for approximately 30% of all ovarian tumours (Young et al 2004). Ninety five per cent of germ cell tumours are dermoid cysts (mature cystic teratomas) and most of the remainder are malignant. Malignant tumours are usually solid, although benign forms also commonly have a solid element. As the name suggests, they arise from totipotent germ cells, and may therefore contain elements of all three germ layers. Most malignant germ cell tumours are composed of primitive or immature elements.

Dermoid cyst (mature cystic teratoma)

Mature cystic teratoma accounts for 27–44% of all ovarian tumours and up to 58% of benign tumours (Koonings et al 1989).

Although most mature cystic teratomas occur in women of reproductive age, they have a wide age distribution (2–80 years) and 5% occur in postmenopausal women.

Most mature cystic teratomas present with a mass, but up to 60% are discovered incidentally. Complications that have been described include torsion of the pedicle and rupture. Rupture is rare (1% of cases) and can elicit chemical peritonitis with granulomatous nodules. The differential diagnosis here has to be made with tuberculosis and carcinomatosis.

Macroscopically, dermoid cysts appear as ovoid tumours, commonly multilocular, with diameters ranging from 0.5 to 40 cm (average 15 cm) with a smooth external surface and filled with sebaceous and hairy material. Not uncommonly, a nodule composed of teeth or bone (Rokitansky protuberance) is found. This area is known to harbour the greatest variety of tissue types, and therefore histological examination is recommended, even when decalcification is required (Rosai 2004).

Histologically, most tumours show derivatives of the three embryonal layers, with ectodermal structures usually predominating and reported in 100% of cases.

The cystic cavities are lined by mature epidermis, with skin adnexae found frequently. Neural (particularly glial), cartilage, respiratory and gastrointestinal tract tissues are also common.

By definition, all these tissues should be histologically mature; very occasionally, one may see foci of immature tissues. The behaviour of tumours with histological foci of up to 21 mm² of immature neuroepithelial tissue is excellent. They have to be distinguished from immature (malignant) teratomas.

'Somatic-type' tumours developing in mature cystic teratoma

Approximately 2% of mature cystic teratomas are known to contain a malignant somatic-type component. The most common is squamous carcinoma, followed by carcinoid tumour and adenocarcinoma. The list includes malignant melanoma, Paget's disease, sarcoma, carcinosarcoma, glioblastoma multiforme and neuroblastoma/primitive neuroectodermal tumour. Even when these behave comparably to their somatic counterparts, they are believed to arise from the germ cell elements.

Not surprisingly, benign somatic-type tumours have also been described, such as blue nevus, sebaceous adenoma, sweat gland adenoma, glomus tumour and prolactinoma.

Mature solid teratoma

These are rare and occur mainly in the first two decades of life. They are usually large and solid with multiple cysts, although multiple small cystic areas are common. By definition, they should be composed entirely of adult tissues. They must be differentiated from immature teratomas which are malignant.

Benign epithelial tumours

Most ovarian tumours (approximately two-thirds of all benign tumours and up to 90% of all malignant tumours) are classified as surface epithelial tumours. Most of these are derived from the ovarian surface epithelium, which in turn develops from the mesothelium-coelomic epithelium that covers the embryonic gonad. It is important to note that in the embryo, this epithelium is continuous with the coelomic epithelium that penetrates the underlying mesenchyme to form the Müllerian duct. This proximity is, in turn, reflected in the various directions of differentiation: towards fallopian tube epithelium in serous neoplasms, endometrial epithelium in endometrioid and clear cell tumours, and endocervical epithelium in some of the mucinous and transitional tumours.

The majority of these tumours are thought to derive from precursor lesions such as serosal inclusions, surface proliferations, metaplasias and endometriosis in the ovary. Although benign epithelial tumours tend to occur at a slightly younger age than their malignant counterparts, they are most common in women over 40 years of age.

Benign serous tumours

Serous tumours are most commonly endophytic (serous cystadenoma), but they may grow to the surface in the form of papillomas.

Serous cystadenomas are the most common type of benign epithelial tumour. Approximately 10% are bilateral. They can occasionally attain huge dimensions (Figure 44.2) and can be uni- or multilocular. Characteristically, the cysts are

Figure 44.2 Macrophotograph of a serous cystadenoma. This specimen measured 40 cm in diameter and weighed over 5 kg.

thin walled and feature watery contents. The cysts may have a smooth lining, but not uncommonly polypoid excrescences can be seen.

Serous surface papillomas appear as polypoid excrescences on the outer surface of the ovaries. Serous adenofibromas are hard and white due to a predominance of the fibromatous component.

Histologically, all three variants are typically lined by epithelium similar to that of the fallopian tube, with variable degrees of ciliation. Psammoma bodies are usually absent.

When papillae are found, these are made almost entirely of stroma. In cystadenofibromas, the fibromatous stroma is prominent. By definition, none of these tumours show cellular atypia.

Benign mucinous tumours (mucinous cystadenoma)

These are the second most common type of ovarian epithelial tumour and tend to be the largest, some of them exceeding 30 cm in diameter and weighing more than 4 kg. The lining epithelium consists of columnar mucus-secreting cells. The most common type is referred to as of intestinal-type lining, in which goblet cells are almost always found. Less frequently, the epithelial lining is of endocervical type. The cyst fluid is generally thick and gelatinous.

A rare complication is pseudomyxoma peritonei which is more often present before the cyst is removed rather than following intraoperative rupture. Pseudomyxoma peritonei is most commonly associated with mucinous tumours of the ovary or appendix. Synchronous tumours of the ovary and appendix are common. There is, however, strong evidence that ovarian mucinous tumours associated with pseudomyxoma peritonei are almost all metastatic rather than primary.

Benign endometrioid tumours

These are ovarian tumours with histological features of benign glands or cysts lined by well-differentiated cells of endometrial type. They are very rare, usually unilateral and have no specific clinical symptoms. The histological diag-

nosis of an endometrioid adenoma or cystadenoma is based on the presence of well-differentiated glands lined by endometrial-type cells with scanty or absent surrounding endometrial stroma. When the latter is prominent, the lesion is classified as endometriosis.

Transitional cell (Brenner) tumours

These are neoplasms composed of epithelial elements histologically resembling urothelium (transitional epithelium). They account for only 1–2% of all ovarian tumours, and are bilateral in 10–15% of cases.

The tumour consists of nests and islands of transitional-type epithelial cells with characteristically grooved nuclei and abundant amphophilic cytoplasm set in a dense fibrotic stroma, giving a largely solid appearance. The nests show central lumina containing mucin and may be lined by columnar cells with a mucinous or ciliated appearance (Figure 44.3).

Despite the transitional appearance of the epithelium, immunohistochemical studies have demonstrated that it lacks a urothelial phenotype, and it closely resembles that of ovarian surface epithelium. As with the other ovarian tumours of epithelial derivation, the whole spectrum from benign to malignant is possible.

Clear cell (mesonephroid) tumours

These arise from serosal cells showing little differentiation, and are only rarely benign. The typical histological appearance is of clear or 'hobnail' cells with varying proportions of fibromatous component. Other cells that may be present include cuboidal, flat, oxyphilic and, rarely, signet ring.

Benign sex cord stromal tumours

Oestrogen-secreting tumours

Granulosa cell tumours

These slowly growing malignant tumours are the most common sex cord stromal tumours occurring in the ovary.

Figure 44.3 Transitional cell (Brenner) tumour showing bland epithelial cells with well-formed lumina. Haematoxylin & eosin, original magnification $\times 20$.

While the great majority occur in postmenopausal women, 5% present in prepubertal or pubertal girls.

Approximately 70% of these tumours secrete oestrogens or, very rarely, androgens. Among postmenopausal women, 60% will present with vaginal bleeding due to oestrogen secretion from the tumour. Endometrial hyperplasia will develop in 25–50% of these women, and 5–10% will develop adenocarcinoma of the endometrium. Approximately 50% of women of reproductive age will complain of menstrual abnormalities, and 16% will have secondary amenorrhoea. In the rare cases when the tumour is secreting androgens, hirsutism may be the presenting feature. Precocious puberty is the usual presentation in young girls. The typical signs of abdominal swelling and pain seen in advanced epithelial ovarian cancer only appear when the granulosa cell tumour is more than 10 cm in diameter.

Thecoma

Thecomas account for less than 1% of all ovarian tumours. They occur in women of postmenopausal age and only a few cases have been reported in women under 30 years of age.

Approximately 70% of thecomas secrete oestrogens but they are less often associated with postmenopausal bleeding than granulosa cell tumours. On the other hand, they are more often associated with endometrial cancer (7% vs 2%). Endometrial hyperplasia is found in a further 19.8% of cases. Postmenopausal bleeding and abdominal pain are the main presenting features. In the presence of luteinized cells, these tumours can secrete androgens and result in hirsutism.

Pure Sertoli cell tumours (sex cord tumour with annular tubules)

These resemble well-differentiated Sertoli-Leydig tumours but contain no Leydig cells. They are benign. The sex cord tumour with annular tubules is a specific variety which resembles gonadoblastomas histologically. Although first described in association with Peutz-Jeghers syndrome, they have also been described in women without this syndrome.

Approximately half of these tumours produce oestrogen and very few secrete androgens. Those secreting oestrogen may cause endometrial hyperplasia, amenorrhoea, menorrhagia or sexual pseudoprecocity. Those associated with Peutz-Jeghers syndrome are usually small, benign, bilateral and partly calcified. In women unaffected by this syndrome, the tumours tend to be larger, unilateral and may be associated with granulosa or Sertoli-Leydig cell tumours. Some are malignant.

Predominantly androgen-secreting tumours

Sertoli-Leydig tumours (androblastoma)

Sertoli-Leydig cell tumour, also called 'androblastoma', is another rare, malignant, sex cord stromal tumour. Like the normal Leydig cell in males, these tumour cells in female ovaries may produce androgens, resulting in virilization. These tumours should be suspected in women in their second or third decades with an adnexal mass and virilization. However, some Sertoli-Leydig tumours can secrete

oestrogen and approximately 80% are inactive. These usually present as unilateral stage I disease when the prognosis is good, even after fertility-conserving surgery, unless the tumour is poorly differentiated.

Adrenal-like tumours of the ovary

The nomenclature of these tumours is a source of great confusion. The current term, 'adrenal-like tumours', is now preferred but many others remain in wide use. The alternative names include 'hilar cell tumours', 'lipoid cell tumours', 'luteomas' and 'adrenal rest tumours'. These are often very small tumours less than 5 mm in diameter. Most are unilateral and benign. Surgical removal will result in reversal of the symptoms of virilization.

Gonadoblastoma

Gonadoblastoma is the most common neoplasm arising in dysgenetic gonads and arises almost exclusively in them. Although gonadoblastomas are benign, more than half are accompanied by malignant germ cell tumours, usually dysgerminomas, which have probably arisen from premalignant cells within the gonadoblastoma. Metastasis of the dysgerminoma component is uncommon but the other combinations can be highly malignant.

They vary in size from a few millimetres to large masses when other germ cell tumours are present. Most are only a few centimetres in diameter. They are often calcified and can be recognized on plain X-ray. More than half are bilateral.

The great majority occur in phenotypic females who are usually virilized. The age range of reported cases is 1–40 years. The clinical presentation may be abnormal genitalia in phenotypic male infants, or primary amenorrhoea with or without hirsutism in phenotypic females. Most have high levels of gonadotrophins due to ovarian virilization failure.

Bilateral gonadectomy is indicated in all these patients because of the risk of malignancy in the non-functioning gonads. This is usually curative for those associated with dysgerminoma, even when large, but chemotherapy will be required for those with other germ cell tumours. The prognosis for such individuals is good, with modern chemotherapy regimens offering 90% survival.

Thecoma–fibroma group of tumours

These arise from the stroma of the ovary and display a spectrum of morphology, from simple fibromas to thecomas. They are classified as fibromas unless an appreciable component of luteinized cells is present.

Fibroma

These are the most common type of sex cord stromal tumour (>66%), with more than 90% occurring in women aged 30 years or older.

Ascites is present in approximately 10% of cases and this occurs in tumours larger than 10 cm in diameter. Approximately 1% of cases are associated with Meigs syndrome (ascites and pleural effusion).

Fibromas are typically uniformly solid, white and rarely show yellowish foci, haemorrhage or necrosis. The classic appearance is that of a spindle cell tumour with variable collagen production and frequent storiform pattern. They are usually cellular but lack atypia or mitotic activity. A subgroup exists in which cellularity is dense but still not atypical (i.e. cellular fibromas). When luteinized cells are present, they should be classified as luteinized thecoma (see below).

Stromal cell tumour with minor sex cord elements

These are rare fibrothecomatous tumours containing scattered sex cord elements (<10%). The latter vary in appearance from granulosa cells to tubules resembling immature Sertoli cells.

Theca cell tumours

Thecomas are benign tumours composed of plump lipid-containing cells resembling the cells of the theca interna of the follicle. The mean age at presentation is 55 years and they typically manifest with symptoms secondary to oestrogen production. They are almost always unilateral, and macroscopically characterized by a solid and bright yellowish cut surface.

Histologically, there is a typical form featuring a varied arrangement of masses of plump eosinophilic or vacuolated cells with intervening fibrous connective tissue. Occasional small nests of granulosa cells can be present.

There is another well-defined histological pattern known as luteinized thecoma commonly seen in a younger age group, with bilateral presentation in which the fibrotic tissue predominates. Ten per cent of these tumours are androgenic.

Theca fibromas

These resemble the largely hormonally inactive fibromas and sclerosing stromal tumours (see below) in that most of them are clinically inactive. Their macroscopy is also indistinguishable from that of the fibromas, as is the histology with the addition of small clusters of theca cells.

Sclerosing stromal tumours

These occur in a younger group than typical thecoma or fibroma (>80% in women under 30 years of age) presenting with symptoms secondary to an ovarian mass, and very rarely give rise to oestrogen-related manifestations. They are unilateral, solid white and clearly demarcated from the adjacent ovarian tissue. The low-power histology is that of pseudolobules separated by bands of sclerotic or oedematous tissue. Within the pseudolobules are two characteristic groups of cells: (i) rounded and vacuolated luteal cells; and (ii) spindle cell fibroblasts. The differential diagnoses here include luteinized thecoma and Krukenberg tumour.

Signet ring stromal tumour

These are rare and are composed of signet ring cells with no mucin content. The numbers of signet ring cells are variable and the main differential diagnosis is Krukenberg tumour.

KEY POINTS

1. Asymptomatic, benign ovarian cysts in young women often resolve spontaneously.
2. Ovarian cysts with a simple appearance on ultrasound and less than 10 cm in diameter are very rarely malignant.
3. Solid ovarian tumours are often malignant; in young women, these are usually germ cell or sex cord stromal tumours.
4. There is no place for ultrasound-directed aspiration of cysts.
5. Laparoscopic removal of ovarian cysts should be confined to those with no features of malignancy.
6. Women over 44 years of age with a unilocular ovarian cyst with a diameter greater than 10 cm or with any other type of ovarian tumour should usually be advised to have a total abdominal hysterectomy and bilateral salpingo-oophorectomy.
7. A bimanual examination under anaesthesia should be performed prior to any surgery for ovarian tumours to confirm that a mass is still palpable.

CARCINOMA OF THE FALLOPIAN TUBE	684	KEY POINTS	686

Carcinoma of the Ovary

Epidemiology

The incidence of ovarian carcinoma varies around the world, with lower rates recorded in Japan (3/100,000 women) and some of the highest rates recorded in the Nordic countries (20/100,000 women). Variations are also noted within Europe, with lower rates occurring in Mediterranean countries (Figure 45.1). In the UK, approximately 7000 cases are reported each year, with a mortality rate of 4500. As such, ovarian cancer remains the most lethal of the gynaecological cancers, and the fourth most common malignant cause of death in women. The majority of women present with disease spread outside the ovaries, normally stage III–IV disease (Table 45.1), and this has a 5-year survival rate of approximately 40%. Ovarian cancer is mainly a disease of postmenopausal women, with the bulk of cases occurring in women aged 50–75 years. The main histological tumours are epithelial in origin, accounting for 90% of cases. Serous tumours are the most common, and as tubal tumours are also serous, accurate identification of the true primary site of disease can be difficult.

Aetiology

The main theory recounted for many years, called the ‘incessant ovulation theory’, is derived from the association between a woman’s number of lifetime ovulations and the risk of ovarian cancer. The greater the number of ovulations, the greater the risk of ovarian cancer. Prevention of ovulation by either pregnancy or use of the combined contraceptive pill should reduce the risk of ovarian cancer, and this has indeed been noted. Some of the proposed explanations for this theory are that the milieu of rapid cellular turnover (in the development of the ovum), the injury caused with release of the ovum and stromal invagination (which occurs at ovulation) contribute to the risk of malignancy. However, more complex factors are likely to be involved. For example, the progesterone in the contraceptive pill is known to cause

apoptosis of ovarian cells, and this is being investigated in a phase II trial by the Gynecologic Oncology Group in high-risk patients to determine the apoptotic effect on ovarian tissues. This may potentially become a preventative therapy in the future.

Infertility

For many years, it has been recognized that there may be an association between infertility and risk of ovarian cancer. The relationship has never been absolutely clarified, and there are many conflicting reports in the literature (Mahdavi et al 2006, Jensen et al 2009). The difficulties mainly relate to the information available, as the types of drugs used, their duration of use and the outcome of pregnancies were not well recorded in many reports. One proposal associating the use of drug-induced ovulation and potential malignant transformation was seen in the increased ovarian cellular dysplasia in ovaries removed from women with a history of in-vitro fertilization treatment (Chene et al 2009). However, further larger longitudinal studies are needed to confirm the situation regarding infertility and ovarian cancer.

Endometriosis

Endometriosis affects approximately one in eight women. The notable tumours associated with endometriosis are ovarian clear cell carcinomas. Endometrioid tumours are also known to have a relationship with endometriosis, but this association is weaker. An interesting fact is that clear cell tumours are most prevalent in Japan, despite the fact that Japan has the lowest incidence of ovarian cancer in the world. The concept that endometriosis is a premalignant condition has been proposed, based on the ability of endometriosis to metastasize, and also as it is found in association with ovarian malignancies. There is a need for further work in this area, but it is interesting to note that women with endometriosis also have a higher relative risk of developing other cancers (Melin et al 2007).

Figure 45.1 Age-standardized incidence and mortality rates for ovarian cancer, European Union, 2002 estimates.

Genetic factors

It is estimated that approximately 10% of all ovarian malignancies are hereditary, and the potential genetic factors in tubal malignancies are becoming increasingly recognized. The latter are rare, but represent sufficient reason to recommend removal of the fallopian tubes when undertaking prophylactic surgery. The two main mutations are *BRCA1* and *BRCA2*. These mutations interfere with the efficacy of p53, and thus permit progression of the malignant process. The greater risk is in women with *BRCA1* who have up to a 40% lifetime risk, compared with 20–25% in those with *BRCA2*. When considering prophylactic surgery, this should be performed before 40 years of age to gain a real benefit. Understandably, if the familial pattern is for a younger age group to develop the disease, siblings will often wish for earlier intervention. The only other familial association is with Lynch type 2 syndrome, with mutations on chromosome 5. In these patients, the family history mainly relates to bowel carcinoma, although the incidence of ovarian cancer is approximately 12% compared with a lifetime risk of approximately 2%. These patients do have a high risk for endometrial cancer, and thus will require the uterus to be removed at the same time if prophylactic surgery is deemed appropriate.

Molecular biology

One aspect of ovarian cancer is the somewhat limited understanding of the tumour biology and the natural history of the condition itself. Most patients present with advanced disease and it is often considered that ovarian cancer has a rapid growth phase, hence the late presentation with a short history of symptoms. Some work on symptoms in ovarian cancer suggests that these may be present some time prior

to diagnosis (Goff et al 2007), and the natural progression of the disease may be different to previous assumptions. However, this requires further research before becoming acceptable.

In ovarian cancer, molecular markers have been researched although there is a lack of true understanding of tumour biology. Tumour vascular proteins (Buckanovich et al 2007) have been shown to have different expression in ovarian malignancies compared with normal, and with the development of antivascular endothelial growth factor therapies with a spectrum of tumour vascular proteins now recognized, further therapies may be developed. Serum mesothelin level is another marker noted to be elevated in ovarian cancer and to have a direct correlation with disease stage, and this could have potential use in screening (Huang et al 2006). Proteomic studies are used increasingly and should yield some valuable information to facilitate the understanding of ovarian cancer (Boyce and Kohn 2005).

Classification of ovarian tumours

Ovarian tumours can be solid or cystic. They may be benign or malignant. In addition, there are those which, while having some features of malignancy, lack any evidence of stromal invasion. These are called 'borderline tumours'.

The most commonly used classification of ovarian tumours was defined by the World Health Organization (Scully 1999). This is a morphological classification that attempts to relate the cell types and patterns of the tumour to tissues normally present in the ovary. The primary tumours are thus divided into those that are of epithelial type (implying an origin from surface epithelium and the adjacent ovarian stroma), those that are of sex cord gonadal type (also known as sex cord stromal type or sex cord mesenchymal type, and originating from sex cord mesenchymal elements) and those

Table 45.1 FIGO staging for ovarian cancer

Stage I	Growth limited to the ovaries
Stage IA	Growth limited to one ovary, no ascites, no tumour on external surface, capsule intact
Stage IB	Growth limited to both ovaries, no ascites, no tumour on external surface, capsule intact
Stage IC	Tumour as for stage IA or B, but tumour on surface of one or both ovaries or capsule ruptured or positive ascites/peritoneal washings
Stage II	Tumour as for stage IC, but growth involving one or both ovaries with pelvic extension
Stage IIA	Extension and/or metastases to the uterus and/or tubes
Stage IIB	Extension to other pelvic tissue
Stage IIC	Tumour as for stage IIA or B, but tumour on surface of one or both ovaries or capsule ruptured or positive ascites/peritoneal washings
Stage III	Tumour involving one or both ovaries with peritoneal implants outside the pelvis and/or positive retroperitoneal or inguinal nodes. Includes superficial liver metastases or histologically proven malignant extension to small bowel/omentum
Stage IIIA	Tumour grossly limited to true pelvis with negative nodes, but histologically confirmed microscopic seeding of abdominal peritoneal surfaces
Stage IIIB	Tumour involving one or both ovaries with histologically confirmed implants of abdominal peritoneal surfaces, none exceeding 2 cm in diameter
Stage IIIC	Abdominal implants greater than 2 cm in diameter and/or positive retroperitoneal or inguinal nodes
Stage IV	Growth of one or both ovaries with distant metastases, e.g. parenchymal liver metastases, or cytologically proven pleural effusion

that are of germ cell type (originating from germ cells). A simplified classification is given in Table 45.2.

Pathology of epithelial tumours

Epithelial tumours are derived from the ovarian surface epithelium, which is a modified mesothelium with a similar origin and behaviour to the Müllerian duct epithelium, and from the adjacent distinctive ovarian stroma. They are sub-classified according to epithelial cell type (serous, mucinous, endometrioid, clear, transitional, squamous); the relative amount of epithelial and stromal component (when the stromal is larger than the cystic epithelial component, the suffix 'fibroma' is added); and the macroscopic appearance (solid, cystic, papillary). They account for 50–55% of all ovarian tumours, but their malignant forms represent approximately 90% of all ovarian cancers in the Western world (Koonings et al 1989). Well-differentiated epithelial carcinomas are more often associated with early-stage disease, but the degree of differentiation does correlate with survival, except in the most advanced stages. Diploid tumours

Table 45.2 Simplified classification of ovarian cancers

Epithelial origin	Serous Mucinous Endometrioid Clear cell Papillary serous Brenner cell Undifferentiated adenocarcinomas and sarcomas
Germ cell origin	Teratomas Mature teratomas Immature teratomas Struma ovarii Carcinoid Dysgerminoma Embryonal cell carcinoma Endodermal sinus Primary choriocarcinoma Gonadoblastoma
Others	Stromal cell cancers Granulosa cell Theca cell Sertoli-Leydig cell

tend to be associated with earlier stage disease and a better prognosis. Histological cell type is not in itself prognostically significant.

Comparing patients stage for stage and grade for grade, there is no difference in survival in different epithelial types. However, mucinous and endometrioid lesions are likely to be associated with earlier stage and lower grade than serous cystadenocarcinomas.

Serous carcinoma

Gross features

The majority of serous carcinomas show a mixture of solid and cystic elements, although a significant minority are predominantly cystic. Serous carcinomas have a propensity to bilaterality, ranging from 50% to 90%, but in only 25–30% of stage I cases.

Microscopic features

The better differentiated tumours have an obvious papillary pattern with unequivocal stromal invasion, and psammoma bodies (calcospherules) are often present. A highly differentiated form of serous papillary carcinoma called 'psammoma carcinoma' contains large numbers of psammoma bodies surrounded by no more than 15 well to moderately differentiated serous cells, and has a favourable prognosis despite the fact that most lesions are found in stage III. None of these features are diagnostic of serous tumours alone. Endometrioid and clear cell carcinomas and, to a lesser extent, mucinous carcinomas may all form papillary structures. The term 'papillary carcinoma of the ovary' should not, therefore, be used as a diagnosis.

At the other end of the spectrum is the anaplastic tumour composed of sheets of undifferentiated neoplastic cells in masses within a fibrous stroma. Occasional glandular structures may be present to enable a diagnosis of adenocarci-

noma. All gradations between these two are seen, sometimes in the same tumour.

Mucinous carcinoma

Gross features

Malignant mucinous tumours comprise approximately 12% of malignant tumours of the ovary. They are typically multilocular, thin-walled cysts with a smooth external surface and contain mucinous fluid. The locules vary in size and the tumour is often composed of one major cavity with many smaller daughter cysts apparently within its wall. Mucinous tumours are amongst the largest tumours of the ovary and may reach enormous dimensions; a cyst diameter of 25 cm is quite commonplace.

A mucinous cystadenocarcinoma may look the same as a benign tumour. Some malignant tumours may exhibit obvious solid areas, perhaps with necrosis and haemorrhage. The more advanced carcinomas will show the stigmata of ovarian malignancy, with adhesions to adjacent viscera and malignant ascites.

Microscopic features

Mucinous adenocarcinomas present a variety of histological appearances. They may contain endocervical-like cells alone, intestinal-type cells alone or a combination of the two, but are more often composed of mucinous cells without distinguishing features. The better differentiated examples are composed of cells that retain a resemblance to the tall, picket-fence cells of the benign tumour, although stromal invasion is present. As differentiation is lost, the cells become less easily recognizable as being of mucinous type and their mucin content diminishes.

Endometrioid carcinoma

Endometrioid carcinomas are ovarian tumours that resemble the malignant neoplasia of epithelial, stromal and mixed origin that are found in the endometrium (Czernobilsky et al 1970). They account for 2–4% of all ovarian tumours. They are accompanied by ovarian or pelvic endometriosis in 11–42% of cases, and a transition to endometriotic epithelium can be seen in up to 30% of cases. The pathologist must distinguish metaplastic and reactive changes in endometriosis from true neoplastic changes.

Gross features

There is little to characterize an ovarian tumour as being of endometrioid type by naked-eye examination. Most are cystic, often unilocular and contain turbid brown fluid. The internal surface of the cyst is usually rough with rounded, polypoid projections and solid areas, the appearances of which are usually distinct from those of the papillary excrescences seen in serous tumours.

Microscopic features

Endometrioid carcinomas resemble the endometrioid carcinomas of the endometrium. The pattern is predominantly tubular and may resemble proliferative endometrium. The epithelium is tall and columnar, with a high nuclear:cytoplasmic ratio. Endometrioid carcinomas of the ovary are more likely to be papillary than primary endometrial carci-

nomas. Five to 10% of cases are seen in continuity with recognizable endometriosis. Ovarian adenoacanthoma, with benign-appearing squamous elements, account for almost 50% in some series of endometrioid tumours.

Associated endometrial carcinoma

It is important to note that 15% of endometrioid carcinomas of the ovary are associated with endometrial carcinoma in the body of the uterus. Although this is sometimes due to a primary tumour in one site and a secondary tumour at the other, these are usually two separate primary tumours.

Clear cell carcinoma

Clear cell carcinomas are the least common of the malignant epithelial tumours of the ovary, accounting for 5–10% of ovarian carcinomas (Anderson and Langley 1970).

Gross features

There is nothing characteristic about the gross appearance of clear cell tumours to distinguish them from other cystadenocarcinomas of the ovary. Most are thick-walled, unilocular cysts containing turbid brown or bloodstained fluid, with solid, polypoid projections arising from the internal surface. Approximately 10% are bilateral.

Microscopic features

Clear cell carcinomas of the ovary are characterized by the variety of architectural patterns, which may be found alone or in combination in any individual tumour. The appearance from which the tumours derive their name is the clear cell pattern but, in addition, some areas show a tubulocystic pattern with the characteristic 'hob-nail' appearance of the lining epithelium. The third major pattern is papillary.

Association with endometriosis and endometrioid tumours

As there is a very strong association between clear cell tumours of the ovary and ovarian endometriosis, and because clear cell and endometrioid tumours frequently coexist, it has been suggested that clear cell tumours may be a variant of endometrioid tumours.

Transitional cell tumours

Transitional cell tumours represent 1–2% of all ovarian tumours and most are benign. The epithelial component resembles urothelium, which may undergo cystic, mucinous or serous metaplasia. The stromal component resembles that of fibromas in benign or borderline lesions, and the malignant counterpart resembles a transitional cell carcinoma.

Borderline epithelial tumours

Approximately 10% of all epithelial tumours of the ovary are borderline tumours, of which 30% are of the mucinous type, followed by the serous type. Other borderline tumours are rare. The histological diagnosis of borderline malignancy can be difficult, particularly in mucinous tumours. These show varying degrees of nuclear atypia and an increase in mitotic activity, multilayering of neoplastic cells and formation of cellular buds, but no invasion of the stroma. Most

borderline tumours remain confined to the ovaries and this may account for their much better prognosis.

Peritoneal lesions are present in some cases and although a few are true metastases, many do not grow and even regress after removal of the primary tumour. Surgical pathological stage and subclassification of extraovarian disease into invasive and non-invasive implants are the most important prognostic indicators for serous borderline tumours, with survival for advanced-stage serous tumours with non-invasive implants being 95.3% compared with 66% for tumours with invasive implants (Seidman and Kurman 2000).

Diagnosis

The symptoms associated with ovarian cancer have come under particular scrutiny over the last few years. The main symptoms are abdominal pain, bloating, postmenopausal bleeding, weight loss and loss of appetite (Bankhead et al 2005, Goff et al 2007). In approximately 10% of cases, there are no symptoms and the disease is found serendipitously, such as following a scan for back pain. Once there is a clinical suspicion of ovarian cancer, investigations can facilitate in defining the risk of malignancy, which will ensure the patient is referred appropriately. This is important as the expertise of the operator will influence the outcome and success of achieving tumour clearance (Junor et al 1999, Tingulstad et al 2003, Earle et al 2006).

The main primary investigations are serum CA125 and abdominal/pelvic ultrasound. These, in conjunction with the menopausal status of the patient, enable calculation of the risk of malignancy. Table 45.3 shows one form of calculation employed. Thus, a high risk of malignancy index (RMI) will capture most advanced ovarian cancers (Jacobs et al 1990). It must be remembered that not all ovarian cancers produce CA125, and mucinous cancers, in particu-

lar, can often have a normal CA125. Equally, a high RMI is not itself diagnostic, and the system is far from perfect. However, it is the only available mechanism at present to triage patients to appropriate specialist centres of care.

In younger patients, the sensitivity of these tests is less as CA125 may be elevated due to menstruation, and scans will find ovulatory cysts which can further confound matters. As well as CA125, serum β -human chorionic gonadotrophin and α -fetoprotein should also be measured in women under 40 years of age as this age group contains most of the germ cell tumours which cause elevation of these markers. Serum carcinoembryonic antigen (CEA) can be useful when there is doubt regarding whether the primary disease originates from the colon. In cases where the CEA level is high, bowel investigations, such as colonoscopy, may be warranted.

Other investigations include computed tomography (CT) of the abdomen and pelvis, which can be used with CA125 to calculate the potential chance of achieving optimum debulking surgery. Magnetic resonance imaging is mainly used in defining the ovarian mass where there is some doubt on CT or ultrasound regarding the origin of the pelvic mass. Chest X-rays are used to detect any metastatic disease, in accordance with the staging recommendations of the International Federation of Gynecology and Obstetrics (FIGO).

Surgery

Surgery remains the main and internationally agreed primary intervention in suspected ovarian cancer. The objectives of surgery are manifold: to obtain a histological diagnosis, to undertake correct staging of the disease, to remove all or as much tumour as possible, and to alleviate symptoms. The procedures commonly undertaken are hysterectomy, bilateral salpingo-oophorectomy, omentectomy, retroperitoneal lymph node sampling, sampling of peritoneal fluids and other biopsies as deemed necessary. Whilst removing all visible disease seems logical, optimum debulking is also undertaken. This surgery is performed to ensure that no residual disease left *in situ* is greater than 1 cm in diameter. This is a unique approach for an intra-abdominal carcinoma and the historic reason is interesting.

In the 1970s, Griffiths published a paper relating survival in ovarian cancer to the amount of residual tumour left in the abdominal cavity. The original publication related to a retrospective series of just over 100 women, which indicated the preferable survival pattern in women with tumour residuum of less than 1.6 cm in diameter compared with those with great tumour loads. The premise for this was the report by Magrath et al (1974) on a similar finding with intra-abdominal Hodgkin's lymphoma. A subsequent prospective study on 26 patients was published, some of whom had undergone primary surgery previously, and some who had also been exposed to chemotherapy (Griffiths et al 1979). Following aggressive surgery, the preferable survival pattern was associated with those who had the lesser tumour residuum. Thus, the optimum debulking procedure became embedded within clinical practice, and many subsequent reports have confirmed this association. Notably, no prospective randomized trials were ever performed to ascertain the validity of this approach, and debate continues about whether those amenable to optimum

Table 45.3 Risk of malignancy estimate

>250	75

RMI, risk of malignancy index.

debulking are also those with the most chemosensitive tumours. Some meta-analyses have been published with variable results. Hunter et al (1992) reported on a cohort of over 6000 women with ovarian cancer, and concluded that the use of platinum agents rather than surgery was a more important factor in enhancing survival outcome. The more recent meta-analysis by Bristow et al (2002) associated the residuum of tumour with survival, and showed that each 10% increase in maximal cytoreductive surgery was associated with a 4.1% increase in median survival time. In Bristow et al's study, unlike that of Hunter et al, all patients were exposed to platinum therapies. Of course, the strength of meta-analyses based on essentially large non-randomized series does permit some questioning of the weight of the final conclusions. Interestingly, a recent randomized trial of complete para-aortic and pelvic lymphadenectomy in advanced ovarian cancer compared with excision of enlarged nodes alone did not reveal any survival benefit (Panici et al 2005).

Nowadays, there is a new approach of supraradical surgery in order to achieve total macroscopic clearance, and these operations can include resection of diaphragmatic lesion, hepatic and splenic metastases, and multiple bowel resections. Patients are carefully selected for these operations, and it remains to be proven whether this radical surgery enhances outcome. Prospective randomized trials are awaited.

An evidence base for practice is always welcome as this can at least attempt to ensure best practice and indeed facilitate patient counselling. Regarding primary surgical intervention, two trials have been undertaken, namely EORTC 55971 and CHORUS. These studies compared standard upfront surgery followed by platinum-based chemotherapy (six cycles) with neoadjuvant chemotherapy (three cycles) then surgery and then a further three cycles of platinum. The EORTC study has only been reported at meetings; peer-reviewed publications are awaited. The CHORUS study is ongoing. These studies are the first randomized trials to address the primary interventions in ovarian cancer (www.eortc.be/protoc/listprot.asp, www.ctu.mrc.ac.uk/studies/).

Fertility-sparing procedures

Whilst radical surgery does relate to the majority of situations, fertility-sparing surgery is advocated in younger women (<40 years) or women who have not completed their families. There are many reasons for this, but primarily younger patients tend to have the rarer ovarian tumours, such as borderline or germ cell tumours (the latter of which are very chemosensitive). In this situation, the affected ovary/cystic areas should be removed and a formal staging procedure — with preservation of fertility — should be undertaken. Naturally, if a standard tumour is found histologically, the option of further surgery can be discussed with the patient.

Surgery for borderline tumours

Specific mention must be made regarding borderline tumours. These are more common in younger patients, and are often only diagnosed at histopathology as the appearances can often be similar to benign ovarian cysts. The

outcome for these tumours is excellent, and radical surgery is not required in most cases, with an estimated relapse rate of 10–15% in 10–15 years. The relapse rate in women who only have a cystectomy is estimated to be approximately 25%, but if a full oophorectomy has been performed, the relapse rate falls to 10–15%. When the patient has completed her family, the role of further surgery is unclear. The relapse rate is small, and there is no evidence that completion surgery would reduce this further. However, there are many 'unknowns' regarding borderline tumours, and a case could be made for completion surgery. It is probably best that expert counselling of patients is undertaken and each case should be managed individually.

Interventional debulking surgery

When optimum debulking is not achieved at the primary operation, a second attempt may be worthwhile. With this objective, three prospective randomized trials were developed. The smallest trial (Redman et al 1994) was stopped prematurely as no advantage was noted at the interim analysis. In this study, optimum debulking was defined as less than 2 cm in diameter. The second study (van der Burg et al 1995) randomized over 300 women who had primary sub-optimal surgery (>1 cm residuum) and were chemosensitive to platinum. Optimum in this study was defined as tumour less than 1 cm in diameter. The study showed a 6 month improvement in median survival in those having a second operation (performed after three of six cycles of platinum treatment). This was the first randomized study published supporting the concept of optimum debulking as a procedure influencing survival in ovarian cancer. The Gynecologic Oncology Group (GOG) (Rose et al 2004) published a similar trial which did not reveal any survival difference with interventional debulking surgery. The trials differed in a few aspects: firstly, paclitaxel was included in the GOG study (not available in van der Burg et al's study), and secondly, more patients in the GOG study had primary surgery by trained gynaecological oncologists, thus influencing the primary optimum debulking rates. The conclusions are therefore conflicting: in European practice, interventional debulking surgery may have a role, but in present-day US practice, it does not seem to have a role if managed by gynaecological oncologists.

Second-look surgery

Second-look laparotomy (SLL) was introduced so that a thorough evaluation of tumour response was possible, and thus ongoing therapy could cease. This was during an era when therapy was continued for over 12 months, and it became evident that iatrogenic malignancies were developing with long-term treatment. The original SLL was performed after 12 months of cytotoxic therapy (Smith et al 1976). In present practice, there are many other non-invasive methods to determine tumour response, but SLL has remained part of routine practice in some countries. One randomized trial has been performed assessing the impact of SLL on survival outcome (Luesley et al 1988), and this did not reveal any benefit. As such, SLL should remain within the context of any relevant clinic trials, rather than part of routine care.

Surgery at relapse

With disease persisting after chemotherapy, or occurring within 6 months of completion of chemotherapy, such disease is deemed resistant and surgery has little role, other than palliation of symptoms. Outside this range, there may be a beneficial effect of further surgery. A series of retrospective studies have identified a group of women in whom surgery at relapse may prolong survival (Jänicke et al 1992, Zang et al 2004, Salani et al 2007). These patients had optimum debulking at primary surgery, a disease-free interval of 12 months and were less than 60 years of age. In this population, there was a greater chance of achieving optimum debulking at second surgery. The most comprehensive study (DESKTOP study) was a multinational study identifying predictive factors for complete tumour clearance in women presenting with relapsed ovarian cancer (Harter et al 2006). From this cohort of 267 women, a 79% prediction rate was achieved with the following variables: good performance status, original optimum debulking, early stage of disease at presentation and no ascites at relapse. In those who had complete resection at second surgery, median survival was 45.2 months compared with 19.7 months in those left with any visible disease. With good predictive models, individuals who may gain survival advantages with surgery at relapse can be identified and will require chemotherapy in conjunction with surgery. It is also well recognized that chemotherapy is more effective for longer disease-free intervals (Blackledge et al 1989); hence, tumour biology, not just surgery, may play an important role. Only a prospective trial will determine the true influence of surgery in this context.

Chemotherapy

Chemotherapy is administered to nearly all women suffering from ovarian cancer. The ICON 1 study (Colombo et al 2003), comparing adjuvant platinum-based chemotherapy with observation in mainly early-stage disease, did not note benefits, even in those with early-stage disease, but no benefit was seen for those with well to moderately differentiated epithelial tumours. It is important that disease staging is performed correctly, as in a cohort from a similar type study (ACTION), it was noted that survival was improved in those receiving adjuvant chemotherapy who were not appropriately staged but assumed to have early-stage disease (Trimbos et al 2003).

The mainstay of therapy remains platinum based, with paclitaxel used in combination in many countries. This would be deemed standard in some countries following a series of studies reporting a superior survival pattern with the addition of paclitaxel to platinum agents in first-line therapy studies (McGuire et al 1996, Piccart et al 2000, Ozols et al 2003). However, in the UK, where ICON 4 (Parmar et al 2003) did not show a benefit associated with the addition of paclitaxel, the guidance of the National Institute for Health and Clinical Excellence (2003) remains open in this regard.

Intraperitoneal therapy

Some years ago, intraperitoneal therapy was used, in that cyclophosphamide was administered into the peritoneal cavity at surgery. Subsequently, it was recognized that to

become active, cyclophosphamide required liver metabolism. Hence the practice ceased. Advocates of the possible survival benefits remained, and in 1996, Alberts et al reported on a randomized controlled trial whereby intraperitoneal cisplatin was given in conjunction with intravenous therapy, and the median survival was increased from 40 to 48 months. There were known side-effects and there was no general acceptance of this type of therapy, mainly due to this and the more complicated manner of administration of cytotoxics compared with intravenous access. However, two further trials (Markman et al 2001, Armstrong et al 2006) which incorporated paclitaxel into the therapy showed increased median survival rates of over 10 months in the intraperitoneal arm. There has been some debate about these trials, in particular that the overall doses employed in the control arms could be considered suboptimal compared with more modern doses, and thus impacting on the survival differences noted (Swart et al 2008).

The issue regarding toxicity also arises, although one study showed that neurotoxicity remained the only variable worse in patients treated with intraperitoneal therapy, compared with intravenous therapy, at 1 year after treatment (Wenzel et al 2007). The recent Cochrane review on this topic concludes that intraperitoneal therapy does afford better survival patterns, but this needs to be measured carefully against toxicity (Jaaback and Johnson 2006) (Table 45.4).

Novel approaches

The approaches to ovarian cancer care are beginning to change, with neoadjuvant chemotherapy increasingly reported (Steed et al 2006). However, the more exciting approaches relate to using a greater number of molecular targets, and indeed developing studies which are more tumour specific. There are ongoing studies for ovarian clear cell tumours, and a study for mucinous tumours is in development. The main molecular targets of therapy are poly(ADP-ribose) polymerase inhibitors, used in *BRCA* mutational tumours such as breast and ovarian cancer (Drew and Calvert 2008). Equally, the results of large trials on targeting vascular endothelial growth factor are awaited with interest, and should hopefully add another approach to therapy (Table 45.5).

Carcinoma of the Fallopian Tube

Fallopian tube malignancies are very rare, although notably there is increasing interest in the proposal that many ovarian serous carcinomas are actually primary fallopian tube carcinomas. However, by virtue of the disease extent at surgery, it is impossible to distinguish the primary source of the cancer. The finding that women with fallopian tube cancers have a 15.9% prevalence of *BRCA1* or *BRCA2* mutations or family histories of early-onset breast or ovarian cancer (Aziz et al 2001) also suggests that some advanced 'ovarian' cancers may actually have originated from the fallopian tubes. Supporting this possibility is the fact that microscopic fallopian tube cancers are found in women undergoing prophylactic surgery for ovarian cancer, indicating a possible hereditary factor (Hirst et al 2009).

Cancers of the fallopian tube can be either primary or secondary. Most tumours involving the fallopian tube are

Table 45.4 The three main phase III intraperitoneal therapy studies

Study	Number	Drugs	Median survival (months)	P-value
Alberts et al	546	IV cisplatin 100 mg/m ² and IV cyclophosphamide	40	<0.02

SLL, second-look laparotomy (after completion of chemotherapy); IDS, interventional debulking surgery (after three cycles of chemotherapy).

metastatic from ovarian cancer, but secondary spread from the breast and gastrointestinal tract also occurs. Primary carcinoma is usually unilateral. It is thought to be extremely rare, comprising only 0.3% of gynaecological malignancies. However, only early fallopian tube carcinomas can be distinguished with certainty from ovarian disease. Most present after the menopause, with the mean age of patients being 56 years. Many cases are nulliparous (45%) and infertility is reported in up to 71% of these women. Tumour spread is identical to that of ovarian cancer, and metastases to pelvic and para-aortic nodes are common.

Pathology

Due to the histological similarity between serous ovarian carcinoma and primary tubal carcinoma, strict criteria must be applied before a diagnosis of tubal carcinoma can be made. Carcinoma of the fallopian tube usually distends the lumen with tumour. The tumour may protrude through the fimbrial end and the tube may be retort shaped, resembling a hydrosalpinx. Histologically, tubal carcinoma is typically very similar to serous adenocarcinoma of the ovary. The predominant pattern is papillary, with a gradation through alveolar to solid as the degree of differentiation decreases.

Staging

The FIGO clinical staging for cancer of the fallopian tube is similar to that used for ovarian cancer. Probably because of the difficulty in distinguishing between advanced ovarian and advanced fallopian tube carcinoma, 74% of fallopian

tube carcinomas are diagnosed at stage I–IIA, while the remaining 26% are diagnosed at stage IIB–IV (Hellström et al 1994).

Clinical presentation and management

Most cases of cancer of the fallopian tube are diagnosed at laparotomy. The diagnosis is seldom considered before surgery. The usual presenting symptom is postmenopausal bleeding, and the diagnosis should be considered particularly if the patient also complains of a watery discharge and lower abdominal pain. Unexplained postmenopausal bleeding or abnormal cervical cytology without an obvious cause demands a careful bimanual examination and pelvic ultrasound. Laparoscopy may be required in doubtful cases.

The management of cancer of the fallopian tube is as for cancer of the ovary, with surgery to remove gross tumour. This will almost always involve a total abdominal hysterectomy and bilateral salpingo-oophorectomy. Omentectomy should be performed. Postoperative chemotherapy will be required with platinum analogues for all but the earliest cases. The treatment of carcinoma metastatic to the fallopian tube is determined by management of the primary tumour.

Results

The overall 5-year survival rate for carcinoma of the fallopian tube is approximately 35%. The prognosis is improved if the tumour is detected at an early stage. The 5-year survival rate for stage I is in the region of 70%, as is that for stage

IA cases. However, survival falls to 25–30% in stages IB–IIIC (Hellström et al 1994). Chemotherapy with platinum agents improves survival.

Conclusions

The management of ovarian and fallopian tube carcinomas involves surgery followed by adjuvant therapy in most cases, which is platinum based. The addition of paclitaxel has

improved survival prospects for some patients with advanced disease. The absolute role of primary surgery and whether or not primary chemotherapy is preferable is being addressed in randomized controlled trials, and some prospective non-randomized trials have also been undertaken in the relapsed setting. Importantly, the greater individualization of therapy and the advent of therapies targeting tumours in a more specific molecular manner means that more sophisticated therapeutic options should become more common in the future.

KEY POINTS

1. Epithelial ovarian cancer usually occurs between the ages of 45 and 65 years. The disease is usually advanced at presentation. It has a poor prognosis except in cases when the disease is confined to the ovaries and is well or moderately well differentiated.
2. Use of oral contraceptives protects against the development of ovarian cancer.
3. Inheritance plays a significant role in approximately 5% of epithelial ovarian cancers. The *BRCA1* gene is associated with 80% of families with both breast and ovarian cancer, but the risk of ovarian cancer alone is variable. *BRCA1* does not appear to be responsible for many sporadic cases of ovarian cancers.
4. Population screening for ovarian cancer is not justified with the techniques evaluated to date.
5. Standard treatment at the present time is surgery followed by a platinum drug-based chemotherapy regimen. This approach allows many women to lead a relatively symptom-free life for periods of up to 2–3 years.
6. Chemotherapy of epithelial ovarian tumours with platinum agents, either alone or in combination, will prolong the patient's life but is unlikely to result in improved long-term survival. Combinations of platinum drugs with paclitaxel may not offer as great an advantage as first appeared to be the case.
7. At present, the biological factors inherent in each tumour, rather than treatment, determine survival.
8. Germ cell tumours occur in young women. They have a much better prognosis than epithelial tumours. Chemotherapy for germ cell tumours is effective even in advanced and recurrent cases, and fertility can be preserved. A young woman with a solid ovarian tumour should be referred to a gynaecological oncologist. If the diagnosis is made postoperatively, she should always be referred to a specialist team.
9. Primary carcinoma of the fallopian tube is treated like ovarian carcinoma.

More than 90% of women presenting to a breast clinic will have benign breast disease (BBD), a heterogeneous condition consisting of a large number of pathophysiological lesions of the different components of the breast (stromal, epithelial, vascular or adipocytes). BBD can be divided into congenital abnormalities, aberrations of normal breast development and involution (ANDI), and conditions secondary to another extrinsic factor. The ANDI classification (1987) of BBD enables a framework and states that breasts are under endocrine control and have a wide range of appearances during reproductive life. The incidence of BBD is difficult to estimate, as women with BBD are often not symptomatic and many do not present for a consultation. However, the incidence of BBD can be estimated by the prevalence in post-mortem examinations and cohort studies.

Stages of Human Breast Development

The lifecycle of the breast involves three main stages: development (and early reproductive life), mature reproductive life and involution. The mammary buds develop during the sixth week as outgrowths of epidermis into the underlying mesenchyme. These mammary buds develop as downgrowths from mammary crests, which are thickened strips of ectoderm extending from the axilla to the inguinal region. During the fourth week, the mammary crests appear and persist in humans in the pectoral region where the breasts develop (Sandler 2006). Several mammary buds developing from each primary bud eventually form lactiferous ducts, and by gestation 15–20 lactiferous ducts are formed. The adipose tissue and fibrous connective tissue of the breast develop from the surrounding mesenchyme. In the late fetal period, the epidermis at the origin of the mammary gland

forms a shallow mammary pit, from which the nipples arise soon after birth due to epithelial proliferation of the surrounding connective tissue of the areola. At birth, the mammary glands of males and females are identical, enlarged and, on occasion, may produce a secretion called 'witch's milk'. The mammary gland remains undeveloped until puberty, with only the main lactiferous duct formed.

Breast development proceeds identically in boys and girls until puberty. During puberty, the female breast enlarges rapidly. The elevated level of circulating oestrogens causes growth of the ductal system; however, progesterones, growth hormone, prolactin and corticoids also play a role. During pregnancy, an increase in the number of lobules and a loss of fat occurs due to raised oestrogen levels and a sustained increase in the level of progesterone. The intralobular ducts form buds that become acini; the lactating breast is composed of dilated acini that contain milk. During weaning, following the suckling stimulus, the breast involutes and the secretory cells are removed by apoptosis and phagocytosis (Howard and Gusterson 2000). The two-layer epithelium of the breast is reformed following weaning. Following successive pregnancies and periods of involution, the terminal duct lobular units (the functional unit of the breast) increase and decrease in size, with an increase and decrease in the number of acini. During involution, the breast stroma is replaced by fat and, as a result, the breast becomes less radiodense, softer and more ptotic (Dixon 1994).

Congenital Abnormalities

These disorders are not uncommon referrals at breast clinics and can cause considerable concern.

Accessory breast tissue and supernumerary nipples

Accessory breast tissue consists of ectopic breast tissue resulting from the failure of the embryonic mammary ridge to regress, commonly found in the anterior axillary line (Qian et al 2008). This occurs in 0.4–0.6% of the population, although is more common in Asian women, and is bilateral in one-third of cases. Accessory breast tissue can cause discomfort, cosmetic problems and restriction in arm movement. This breast tissue may become prominent during pregnancy, and both benign and malignant conditions may occur within this tissue. An explanation of the 'abnormality' and reassurance is often all that is required, and surgical excision should be reserved for symptomatic patients as a good cosmetic outcome is difficult and associated with significant morbidity.

The nipple is normally positioned slightly inferomedial to the centre of the breast. The nipple areola complex is composed of pigmented squamous epithelium, but also contains a layer of circumferential smooth muscle and sebaceous glands which open through small prominences (Montgomery tubercles) surrounding the periphery of the areola. Common congenital malformations, including supernumerary nipple or nipples, may be found along the milk-line extending bilaterally from the axilla to the groin. Most commonly, these supernumerary or accessory nipples are found below the breast and above the umbilicus, with the most inferior location being the proximal medial thigh. Should an accessory nipple become irritating, excision can be offered.

Breast hypoplasia and Poland syndrome

Breast hypoplasia is failure of a breast to fully develop, which is usually unilateral but may be bilateral. Breast asymmetry usually only requires reassurance, but if asymmetry is significant, augmentation of the affected side with or without the contralateral breast may be required. Breast hypoplasia may be associated with tubular breasts; a deformity that can affect one or both breasts as a result of constriction at the base of the breasts, limiting growth. Surgical intervention in this group is often difficult and unsatisfactory.

Poland syndrome is a group of conditions in which amastia develops with varying degrees of absence of the pectoralis muscles and syndactyly, affecting one in 30,000 live births (Figure 46.1). It was first described by Alfred Poland in 1841, whilst he was a medical student at Guys Hospital, London (Ram and Chung 2009). Subsequent reports have added numerous additional components to the syndrome including mammary hypoplasia, costal cartilage defects and rib defects. One study evaluating 75 patients showed 100% with an absence or hypoplasia of the pectoralis major, 67% with a hand abnormality, and 49% with athelia (congenital absence of one or both nipples) and/or amastia (breast tissue, nipple and areola is absent; differs from amazia which only involves the absence of breast tissue, and the nipple and areola remain present) (Katz et al 2001). The syndrome is almost always unilateral, with the right side more often affected than the left side, and is more common in men than women (3:1). Patients with Poland syndrome often request reconstruction of the muscular

defect, producing symmetry and improving psychological well-being. This can be performed with an ipsilateral latissimus dorsi pedicled flap with or without an implant.

Aberrations of Normal Development and Involution

Most BBD arises from normal physiological processes, ranging from mild abnormality (aberration) to severe abnormality (disease). The breast passes through three phases relating to circulating hormone levels: development, cyclical change and involution.

Juvenile hypertrophy

Generalized hypertrophy of the adolescent breast is known as 'juvenile hypertrophy' and, in some cases, 'juvenile gigantomastia'. It can be bilateral or unilateral and is characterized by diffuse enlargement of the breast without nodularity or discrete masses. Growth of the breast is usually rapid and can be significant. Breasts can grow to be as large as 13–23 kg. The pathophysiology is thought to involve an abnormal response of the breast to hormonal stimulation, but the exact mechanism is not known. Hypertrophy is not associated with elevation in serum oestrogen, progesterone, prolactin or gonadotropins, and evidence is lacking for an increased number of oestrogen receptors in the breast. The weight of the breasts can cause back and neck pain, shoulder grooving, poor posture and an inability to perform daily tasks.

Psychological stress and social embarrassment are also common in these young women in whom body image is developing. Histologically, the breast shows stromal and ductal hyperplasia with dilated ducts. The treatment in most cases is reduction mammoplasty, for which there are a number of techniques. Depending on the timing of the operation in relation to puberty, there is a risk of recurrent hypertrophy of the remaining breast tissue, which may require further surgery. The closer surgery is to the end of

puberty, the greater the chance of a permanent reduction in size. Hypertrophy of remaining breast tissue can occur with pregnancy. Several reports have shown that giving danazol during rapid breast enlargement has some benefit.

Premature breast development between the age of 6 months and 9 years requires investigation for signs of precocious puberty. Pubic hair, accelerated bone growth and genital development may be signs of an ovarian or adrenal tumour. Isolated thelarche [first stage of secondary (post-natal) breast development] can be observed, but patients should undergo careful physical examination every 6–12 months to look for other signs of puberty. Isolated breast development in the prepubertal child should regress within 1–2 years. Persistent or progressive development in the prepubertal child that does not regress requires endocrine assessment.

Fibroadenoma

Fibroadenomas are classified as an aberration of normal development, arising from the hormone-sensitive terminal ductal lobular unit, typically composed of stromal and epithelial cells. The stromal element defines its behaviour and classification.

Simple fibroadenoma

These are discrete, firm, highly mobile, benign breast masses which may present symptomatically or as an incidental screening finding. Fibroadenomas usually present unilaterally; however, in 20% of cases, multiple lesions may present in the same breast or bilaterally. They are found most commonly at the time of greatest lobular development in women aged 15–35 years. The encapsulation explains the motility of the masses, making them appear more superficial than they truly are (Figure 46.2). Fibroadenomas develop from the special stroma of the lobule. They are hormone dependent, lactate during pregnancy and involute with the rest of the breast in the perimenopause (Hughes et al 1987). A direct association has been reported between use of the oral contraceptive pill before the age of 20 years and risk of fibroadenoma. The Epstein–Barr virus is thought to play a causative role in the development of this tumour in immunosuppressed patients (Kleer et al 2002). Observation of fibroadenomas in younger women showed that 55% do not change size, 37% get smaller and 8% increase in size. Fifty percent of fibroadenomas contain other proliferative changes such as adenosis, sclerosing adenosis and duct epithelial hyperplasia; these are known as ‘complex fibroadenomas’. Complex fibroadenomas, but not simple fibroadenomas, are associated with an increased risk of breast cancer (Carter et al 2001). Fibroadenomas in older women or in women with a family history of breast cancer have a higher risk of associated breast cancer (Dupont et al 1994, Shabtai et al 2001).

Fibroadenomas over 5 cm in size are known as ‘giant fibroadenomas’, and are seen more commonly in women of African origin. Cancers rarely appear within a fibroadenoma. Patients with a histologically confirmed fibroadenoma can be managed conservatively, with follow-up imaging at 6 months to confirm that the lesion is not increasing in size. Excision is recommended if the mass increases in size, if it

Figure 46.2 Fibroadenoma. Oval area of reduced echogenicity (arrows) with bright up due to good through transmission of sound and brighter echos deep to the fibroadenoma (arrow heads).

Image courtesy of Dr William E. Svensson, Consultant Radiologist, Imperial College NHS Trust, London, UK.

is larger than 3–4 cm or at the patient's request. Recurrence is rarely due to incomplete excision, and is often due to an undiagnosed adjacent mass. A minimally invasive technique, such as ultrasound-guided cryoablation, is a treatment option for fibroadenomas in women who do not wish to have surgery (Caleffi et al 2004). Rapid growth of a fibroadenoma can occur in adolescence (juvenile fibroadenoma) or in women of perimenopausal age. Juvenile fibroadenomas usually present as painless, solitary unilateral masses over 5 cm in size (reaching up to 15–20 cm). Although benign, surgical excision of these masses is advised (Wechselberger et al 2002).

Phyllodes tumour

Johannes Muller (1838) first described a large mammary tumour with a cystic appearance and leaf-like growth pattern; he named this ‘cystosarcoma phyllodes’. Treves and Sunderland (1951) proposed that benign, premalignant and malignant forms of this disease existed. The term ‘phyllodes tumour’ (PT) was adopted by the World Health Organization in 1981 to describe this rare fibroepithelial lesion, which accounts for less than 1% of all breast neoplasms. They are less common than fibroadenomas (ratio 1:40), from which they need to be distinguished. PTs can present in women of any age, including adolescents and the elderly, but the majority occur in women aged 35–55 years; the median age of presentation is 45 years. PTs present clinically as a well-circumscribed, mobile mass which may be growing rapidly. The size of presentation of PTs is larger than that for fibroadenomas, although with increased breast awareness and the advent of breast screening, there has been a trend towards smaller tumours. Other signs and symptoms include dilated skin veins, blue skin discolouration, nipple retraction, fixation to the skin or pectoralis muscle, and pressure necrosis of the skin. Palpable axillary lymphadenopathy has been identified in up to 20% of patients, but axillary metastatic involvement is rare. PTs are more commonly found in the upper outer quadrant of the breast. Prevalence is higher in Latin American White and Asian populations. Certain clinical features may raise the index of suspicion,

including a sudden increase in a longstanding breast mass, a fibroadenoma over 3 cm in size in a patient aged over 35 years, lobulated appearance on mammography, cystic areas within a solid mass on ultrasonography, and indeterminate features on fine needle aspiration cytology (FNAC) (Jacklin et al 2006). PTs are often not clinically distinguishable from fibroadenomas.

PTs often mimic fibroadenomas at mammography, appearing as large, well-circumscribed, oval or lobulated masses with rounded borders, and a radiolucent halo or coarse microcalcifications. Ultrasonography often shows a non-homogeneous, solid mass, with low-level internal echoes and smooth walls. Discovery of a cyst within a solid mass is highly suggestive of a PT. Dynamic enhancement patterns on magnetic resonance imaging may be useful for the diagnosis of tumours over 3 cm in size, although the role has not been fully elucidated.

Diagnosis of PTs by FNAC is associated with a high false-positive rate due to the heterogeneity of the tumours. The risk of sampling error is reduced following a core biopsy. Criteria have been formulated to help physicians to select patients for core biopsy — the Paddington Clinicopathologic Suspicion Score (Jacklin et al 2006). Twenty-five percent of PTs are categorized as malignant and more than 50% are categorized as benign, with a number of prognostic factors implicated in the risk of local and distant recurrence including tumour size, grade and margin status. Benign PTs have the potential to recur locally, and rarely present at distant sites. Despite having an increased risk of distant spread (20%), malignant lesions have a 15-year survival rate of 89%.

Wide local excision with margins over 1 cm is the preferred primary treatment of PTs, as microprojections of tumour frequently extend into the pseudocapsule of normal tissue surrounding the lesion. One study in which 99% of the patients had histologically negative margins still reported an 8% local recurrence rate, suggesting that risk of recurrence can be reduced with negative margins but not eliminated completely. Adjuvant chemotherapy and hormonal therapy has no role in the treatment of PTs, and there is no high-level evidence to support the role of radiotherapy in these lesions. Local recurrence will occur in 15% of patients with PTs, mostly within 2 years of initial surgery (range 1 month–17 years). These tumours generally present with the same histology, and guidelines advise re-excision with wide margins; the role of adjuvant radiotherapy is controversial. Metastatic lesions often develop within 3 years at sites including the lung, bone and abdominal viscera, with a poor prognosis and average survival of less than 2 years.

Nipple Discharge

Nipple discharge accounts for approximately 5% of breast clinic referrals. Important features to determine include whether the discharge is from one duct or several, is spontaneous or induced, and affects one or more breasts. It is important to note the colour, frequency and consistency of the discharge, with the aim of determining whether the cause of the discharge is physiological or pathological. Fluid can be elicited from the nipple by gentle manipulation in the majority of women (85%) regardless of age or health. Should

the nipple discharge present with a mass, the management is directed to the diagnosis of the breast mass. Although nipple discharge usually has a benign aetiology, some studies have shown that the incidence of breast cancer is between 9.3% and 21.3% in women with pathological nipple discharge.

Assessment includes a thorough breast examination to ascertain whether a breast lump is present. Firm areola pressure can identify a dilated duct (and pressure over the duct can produce discharge). Firm digital pressure of the nipple can elicit fluid, and the site and character of the discharge can be noted. The presence of blood can be determined by testing the discharge for haemoglobin; however, only 10% of patients with bloodstained discharge will have an underlying malignancy. The sensitivity of Hemocult (a guaiac reagent strip test for occult blood) has been shown to be only 50%. Mammography should be performed in women over 35 years of age as part of the assessment, with a sensitivity of 57% in this group. Ultrasonography can identify malignant lesions and papillomas. If no abnormality is found, any patient presenting with spontaneous single duct discharge should undergo surgery if it is associated with a mass, bloodstained or persistent (more than twice per week). Postmenopausal women with new serosanguineous discharge should also undergo surgery.

Ductoscopy allows direct visualization of the discharging duct, and biopsy, by a microendoscope, was investigated by Okazaki in the early 1990s. The procedure is carried out using local anaesthesia (topical local anesthetic cream plus intradermal local anesthetic injection at the areolar margin) and has no significant complications (Escobar et al 2006). An endoscope is inserted through the duct opening on the nipple surface after dilating the duct with a probe (e.g. lacrimal dilator), and saline solution is injected into the duct through the channel to widen it and facilitate the passage of the endoscope, enabling visualization of the intraductal space (Escobar et al 2006). Whilst ductoscopy can be used as a diagnostic and therapeutic addition in patients with nipple discharge, there is no evidence to support its use in the management or early detection of breast cancer.

A major limitation of nipple aspirate fluid is that insufficient material is present for cytology, which prompted the development of ductal lavage. By cannulating and irrigating a discharging duct, ductal lavage fluid can be sent for cytology (increasing cell yield by 100 times compared with ductal discharge). Ductal lavage is not sufficiently accurate for the assessment of patients with known breast cancers. One study has reported sensitivity of 17% for the diagnosis of breast cancer in the setting of a known malignancy. A number of groups are using a genomic approach to investigate nipple aspirate for malignant potential. Methylation of promoter regions of tumour suppressor genes is common in breast cancer, resulting in silencing of tumour suppressor genes. Promoter hypermethylation has been demonstrated in nipple aspirate fluid of patients with ductal carcinoma in situ (DCIS) and invasive ductal carcinoma. Nipple aspirate may become a surrogate for breast tissue, enabling many types of cellular and genomic assessment without a biopsy. Further advances in intraduct technology and techniques may add to our understanding of the biological progression of breast cancer, its prevention and treatment.

The aetiology of non-surgically-treated nipple discharge can be grouped into four categories:

- Physiological — includes lactation in the peripartum period, normal breast secretions which may be elicited by manual stimulation of the breast (note: all spontaneous discharge must be fully assessed by a clinician).
- Pathological endocrine causes (increased prolactin secretion or failure of normal prolactin inhibition) — prolactinomas are the most common secretory tumours of the anterior pituitary causing unilateral/bilateral galactorrhoea. Primary hypothyroidism can cause hyperprolactinaemia; rarely, bronchogenic carcinomas may result in ectopic production of prolactin. Other causes of increased prolactin include head trauma, encephalitis and hypothalamic infiltration (sarcoid/tumour).
- Pharmacological — several drugs can increase prolactin and galactorrhoea including: (1) psychoactive medication (e.g. phenothiazines, tricyclic antidepressants, selective serotonin reuptake inhibitors, haloperidol and anxiolytics), (2) antihypertensives (e.g. calcium channel blockers, methyldopa, reserpine), (3) gastrointestinal medication (e.g. metoclopramide, cimetidine, ranitidine), (4) oestrogens (conjugated oestrogen and medroxyprogesterone acetate), (5) anaesthetics and (6) amphetamines and marijuana.
- Idiopathic — galactorrhoea is a bilateral, copious milky-white discharge from multiple ducts. If the prolactin level is raised (>1000 mIU/l), the cause may be secondary to medication or a primary tumour. If the prolactin level is normal, the patient can be reassured. Excision of the subareola ducts may be required in the case of persistent symptoms.

Duct ectasia

Duct ectasia is characterized by dilatation and shortening of the terminal ducts within 3 cm of the nipple. It is a common condition, increasing with age; post-mortem findings have reported duct ectasia in 24% of all women and in 43% of

women over 60 years of age. It may present as a white or green viscous discharge, occasionally bloodstained. The colour of discharge varies significantly and can differ between ducts in the same breast. The nipple discharge may be either spontaneous or expressed by the patient. It typically comes from two or three ducts and may be bilateral. It is not known whether the primary event is inflammatory in origin, or whether lactation and stagnation of secretions leads to a secondary inflammation.

Intraductal papilloma and papillomatosis

Intraductal papillomas are benign intraductal proliferations, usually found in the major ducts beneath the nipple (lactiferous sinuses); however, they can be found anywhere in the breast. The term 'papilloma' describes the fibrovascular cores covered by a double layer of cells comprising an outer myoepithelial layer and an inner luminal cell layer (Mallon et al 2000). The cells are cytologically benign. Squamous and apocrine metaplasia are common findings. There are three types of intraduct papilloma: solitary, multiple or juvenile papillomas. Solitary duct papillomas are the most common; these occur in large ducts (within 5 cm of the nipple) and present with either bloody or a serous single duct discharge (Figure 46.3). Two studies have demonstrated a correlation between the presence of atypical ductal hyperplasia (ADH) in a papillary lesion on needle core biopsy and the presence of invasive or in-situ carcinoma of the breast in the excisional biopsy (Agoff and Lawton 2004, Ivan et al 2004). It has been suggested that the risk of recurrence of papilloma is related to the presence of proliferative breast lesions in the surrounding breast tissue (MacGrogan and Tavassoli 2003). Papillomatosis (multiple intraductal papillomas; 10% of intraductal papilloma) is defined as a minimum of five discrete papillomas within a localized segment of breast tissue. Papillomatosis tends to occur in younger patients and is less often associated with nipple discharge. Multiple papillomas are more frequently peripheral, bilateral, present as a palpable mass and have a higher probability of having an in-situ or invasive carcinoma than central papilloma. Thorough radiological imaging of the contralateral breast is required

Figure 46.3 Intraduct papilloma. (A) The intraduct papilloma can be seen within the slightly dilated duct (arrow heads) allowing it to be differentiated from other lesions of reduced heterogeneous echogenicity. Intraduct papillomas are often quite vascular, which can be demonstrated with colour Doppler (B).

to exclude malignancy (Ali-Fehmi et al 2003). Multiple papillomas are associated with an increased risk of developing subsequent breast cancer (Krieger and Hiatt 1992, Page et al 1996, Levshin et al 1998). Juvenile papillomatosis is a rare condition defined as severe ductal papillomatosis occurring in women under 30 years of age (median age 20 years). It often presents as a discrete mass up to 8 cm in diameter, and consists of a mixture of cysts, nodules of sclerosing adenosis and complex intraduct proliferations containing myoepithelial cells and luminal cells. Due to the holes seen in the cut surface of the tumour, it has been called 'Swiss cheese disease'. A number of studies have suggested an association between juvenile papillomatosis and familial breast cancer; therefore, long-term follow-up is advised (Bazzocchi et al 1986).

Bloody nipple discharge in pregnancy

Bloody nipple discharge during pregnancy or lactation is a common finding. It occurs in 20% of women who present with nipple discharge during pregnancy, and is likely to be due to the increased vascularity of the developing tissue. It is benign and requires no specific treatment.

Ductal carcinoma *in situ*

Approximately one-third of symptomatic ductal carcinomas present with nipple discharge, and invasive cancers rarely cause nipple discharge in the absence of a mass. DCIS is thought to be responsible for approximately 10% of cases of unilateral nipple discharge.

Surgical treatment of nipple discharge

Historically, all patients with pathological nipple discharge are offered an operation. Patients with surgically significant nipple discharge aged 40 years or more are recommended to undergo Hadfield's procedure (radical subareolar duct excision). Patients under 40 years of age with persistent discharge are given the option of microdoectomy, particularly if they are intending to breast feed.

Microdoectomy

Microdoectomy involves the removal of a single duct through a circumareolar incision. Expression of nipple discharge is performed when the patient is in theatre, and the duct is then cannulated with a lacrimal probe. The probe aids identification of the discharging duct and enables the surgeon to dissect it from the surrounding tissue. At least 2–3 cm of duct should be removed and the excised duct should be opened and the distal remnant inspected. The procedure should not damage the surrounding ducts and should therefore allow subsequent breast feeding.

Total duct excision (Hadfield's operation)

In women of non-childbearing age, total/major duct excision is a surgical option for single duct discharge, multiple duct discharge and periductal mastitis. The procedure involves division of ducts underneath the nipple and

removing the breast tissue to a depth of 2 cm under the nipple–areolar complex through a circumareolar incision. Complications include nipple necrosis, nipple inversion and reduced nipple sensation. Recurrence of periductal mastitis may occur if all of the ducts are not removed during the operation. The procedure can also be performed in women having a cosmetic nipple eversion procedure.

Mastalgia

The majority of women will suffer from mastalgia (breast pain) at some point in their lives. It is important to differentiate true mastalgia (originating from the breast) from referred pain. Referred pain is often unilateral, reproduced by pressure on the chest wall and associated with activity. Non-steroidal anti-inflammatory drugs, either orally or topically, can improve these symptoms. True breast pain is associated with swelling and nodularity, and can resolve spontaneously. This pain is often worse before menstruation and is relieved after the cessation of menstruation. It is not important to differentiate between non-cyclical and cyclical mastalgia as the treatment is the same. Symptoms may be exacerbated by exogenous hormones (hormone replacement therapy or oral contraceptive pill) and the perimenopausal state. The cause of mastalgia is unknown, but a number of theories have been postulated including excess oestrogen or prolactin, and low progesterone.

Assessment includes history, examination and, in women over 35 years of age, mammography. Five percent of women with breast cancer complain of pain, whilst only 2.7% of women with breast pain as their only complaint will have an underlying breast cancer. A pain chart can allow better interpretation of the pattern of pain and gives an objective evaluation of treatment.

The majority of patients can be managed by exclusion of cancer and reassurance. Evening primrose oil (EPO) was previously used in the treatment of mastalgia, but has recently been withdrawn from prescription by the Medicines Control Agency. A recent randomized, double-blind controlled trial of 121 women comparing EPO and fish oil with control oils in the treatment of mastalgia showed no clear benefit from either EPO or fish oils (Blommers et al 2002). This study showed that 33% of women with cyclical mastalgia and 17% of women with non-cyclical mastalgia showed an improvement in symptoms with EPO compared with the control group (46% and 17% improvement, respectively). Other agents have shown some benefit, including phytoestrogens (soya milk) and *Vitex agnus-castus* (a fruit extract). A reduction in dietary fat intake has also been shown to improve symptoms. Second-line treatments include tamoxifen 10 mg daily and danazol 200 mg daily. Tamoxifen given in the luteal phase of the menstrual cycle controlled mastalgia in 85% of women, with recurrent pain noted in 25% of patients at 1 year. Tamoxifen has been found to be superior to danazol with a better toxicity profile. Fifty-three percent of patients receiving tamoxifen compared with 37% of patients receiving danazol were pain-free after 1 year. It is important to note that tamoxifen is not licenced for use in mastalgia. Due to the high toxicity rate (80%), bromocriptine is no longer used in the treatment of mastalgia.

Fibrocystic Change

Fibrocystic change (FCC; also called fibrocystic disease, cystic mastopathy, chronic cystic disease, mazoplasia, Reculus's disease) is the most common benign disorder of the breast, affecting women between 20 and 50 years of age (Cole et al 1978, Hutchinson et al 1980, Cook and Rohan 1985, La Vecchia et al 1985, Bartow et al 1987, Sarnelli and Squartini 1991, Fitzgibbons et al 1998). FCC is observed in approximately 50% of women clinically and in 90% histologically (Love et al 1982). The most common symptoms of FCC are breast pain and tender nodularity. FCC is thought to be due to a hormonal imbalance, particularly the predominance of oestrogen over progesterone; however, the pathogenesis is not completely understood (Dupont and Page 1985). FCC is made up of cystic lesions (macrocytic and microcytic) and solid lesions, and includes adenosis, epithelial hyperplasia with or without atypia, apocrine metaplasia, papilloma and radial scar. FCC can be classified into non-proliferative lesions, and proliferative lesions with or without atypia (atypical hyperplasia) (Dupont and Page 1985).

- Non-proliferative lesions — cysts, papillary apocrine change, epithelial-related calcifications, duct ectasia, non-sclerosing adenosis, periductal fibrosis and mild epithelial hyperplasia.
- Proliferative lesions without atypia — moderate/florid ductal hyperplasia of usual type, sclerosing adenosis, intraduct papilloma, papillomatosis and radial scar.
- Proliferative changes with atypia — ADH and lobular hyperplasia.

Non-proliferative lesions are not associated with an increased risk of developing breast cancer; however, women with proliferative disease without atypia and with atypia are at greater risk of breast cancer (relative risk 1.3–1.9 and 3.9–13.0, respectively) (Dupont and Page 1985, Palli et al 1991, Dupont et al 1993, Marshall et al 1997). Age is thought to play a key role, with the risk of breast cancer in young women with a diagnosis of atypical epithelial proliferation twice that of a woman over 55 years of age with a similar diagnosis (Hartmann et al 2005).

Breast cysts

Breast cysts are fluid-filled, ovoid/round structures affecting one-third of women between 35 and 50 years of age. The majority are subclinical 'microcysts', but approximately 20–25% are palpable 'macrocyts' which are a common presentation at breast clinics (Haagenson 1986). Macrocyts are often multiple and appear in the fifth decade. Cysts are derived from the terminal duct lobular unit, and in most cysts, the epithelial lining is either flattened or absent (non-apocrine cysts). In a few cysts, the apocrine epithelial lining can be observed (apocrine cysts). Apocrine cysts have a higher recurrence rate than non-apocrine cysts (Dixon et al 1999). Breast cysts have mammographically characteristic halos, but cannot be reliably distinguished from solid masses; therefore, ultrasonography and fine needle aspiration (if indicated) are used for diagnosis (Figure 46.4). Ultrasonography can also distinguish between simple and complex cysts, and a cyst wall with any projections may

Figure 46.4 Multiple breast cysts within the breast demonstrated on an extended field to view ultrasound image. Cysts contain fluid and are usually anechoic and exhibit marked bright up (increased echogenicity) deep to them.

indicate carcinoma or an intracystic papilloma which necessitates either a core needle biopsy or a surgical excision biopsy (Vargas et al 2004, Houssami et al 2005). Complex (complicated/atypical) cysts, reported in approximately 5% of all breast ultrasounds, are characterized by internal echoes or thin septations, thickened and/or irregular wall, and absent posterior enhancement (Houssami et al 2005). Asymptomatic cysts are left alone but large painful cysts can be aspirated to dryness. Any bloodstained fluid should be sent for histology, and if a palpable mass is still evident after aspiration, further investigations are indicated. Cysts may recur following aspiration. There is a slightly increased relative risk of breast cancer in women with cysts.

Adenosis

Adenosis of the breast is characterized by an increase in either the number or size of glandular components, usually involving the lobular units. Sclerosing adenosis is a benign lesion of disordered acinar, myoepithelial and connective tissue which can mimic carcinoma (Jensen et al 1989). It can present as a palpable mass or as a suspicious finding at mammography, and is associated with other proliferative lesions including epithelial hyperplasia, papillomas, complex sclerosing lesions, apocrine changes and calcification. A number of studies have shown that it is a risk factor for invasive cancer. Microglandular adenosis is characterized by a proliferation of small, round glands distributed irregularly within dense fibrous and/or adipose tissue. Notably, microglandular adenosis lacks the outer layer of myoepithelia seen in other tissue types of adenosis. This lack of myoepithelial layer makes it difficult to differentiate from tubular carcinoma (Eusebi et al 1993). The absence of epithelial membrane antigen staining in the luminal epithelial cells, and the presence of basal lamina encircling glandular structures demonstrated by laminin or type IV collagen immunostaining distinguishes between microglandular adenosis and tubular carcinoma (Eusebi et al 1993). Microadenosis has a tendency to recur if not completely excised, and although it is defined as benign, there is growing evidence of the poten-

tial of this lesion to become invasive carcinoma (Acs et al 2003). Apocrine (adenomyoepithelial) adenosis is a variant of microglandular adenosis. Apocrine adenosis describes a wide spectrum of lesions, and in this case describes apocrine changes in the specific underlying lesion (deformed lobular unit, sclerosing adenosis, radial scars and complex sclerosing lesions) (O'Malley and Bane 2004). Tubular adenosis is a rare variant of microglandular adenosis that can be distinguished from tubular carcinoma by the presence of an intact myoepithelial layer around the tubules (Lee et al 1996).

Metaplasia

Apocrine metaplasia is characterized by columnar cells with granular, eosinophilic cytoplasm and luminal cytoplasmic projections (Guray and Sahin 2006). These cells line dilated ducts and are more frequently seen in younger women. When the nuclei of the apocrine cells display significant atypia, this is known as 'atypical apocrine metaplasia'. Clear cell metaplasia of the breast is morphologically similar to clear cell carcinoma; however, its immunohistochemical staining is similar to an 'eccrine' sweat gland (Vina and Wells 1989).

Epithelial hyperplasia

Epithelial hyperplasia is the most common form of proliferative breast disease. There are two types of epithelial hyperplasia — ductal and lobular epithelial hyperplasia — and these can be difficult to distinguish. It can also be difficult to distinguish between usual ductal/lobular hyperplasia and atypical ductal/lobular hyperplasia.

Ductal hyperplasia

Normal breast ducts are lined by two layers of cuboidal cells with specialized luminal borders and basal contractile myoepithelial cells. Epithelial hyperplasia is defined as an increase in cells within the ductal space. The degree of architectural and cytological features of the proliferating cells further classifies hyperplasia. Usual ductal hyperplasia has an increase in the number of cells without architectural distortion, and is not associated with an increased risk of breast cancer. Mild hyperplasia of usual type denotes a three- to four-cell layer of proliferating cells, whereas moderate hyperplasia describes a proliferating layer more than four cells thick. In florid hyperplasia, the lumen is distended and may be obliterated. The most important cytological feature of mild, moderate and florid hyperplasia is the mixture of cell types and variation in appearance of epithelial cells and their nuclei (Koerner 2004).

ADH is a type of hyperplasia that mimics low-grade DCIS. It is a rare condition seen in 4% of symptomatic benign biopsy lesions, and is often small and focal, involving a small part of the duct or a few ducts (Guray and Sahin 2006). More ADH lesions are being detected with the increased use of mammography. Thirty-one percent of biopsies due to microcalcifications show ADH (Pinder and Ellis 2003). Patients with ADH have a four to five times increased risk of developing breast cancer compared with the general population, and the risk is 10 times greater compared with the general population if the patient has a first-degree relative

with breast cancer. The increased risk of breast cancer is higher in both the ipsilateral and contralateral breasts (Page et al 1985, Tavassoli and Norris 1990). Women with ADH have an increased risk of developing cancer within 10–15 years of diagnosis, with this risk declining after 15 years (Page et al 1985, Dupont and Page 1989). Premenopausal women with ADH have a significantly higher risk of developing breast cancer than postmenopausal women. Routine follow-up of women with ADH is recommended.

Lobular hyperplasia

Atypical lobular hyperplasia and lobular in-situ neoplasia are collectively termed 'lobular neoplasia' because, unlike ductal lesions (which are heterogeneous), the histological features of lobular epithelial proliferations are very similar. The significant difference between lobular in-situ neoplasia and atypical lobular hyperplasia is the degree and extent of epithelial proliferation. Lobular neoplasia is a rare breast condition more prevalent in perimenopausal women, which rarely presents clinically and is often found as an incidental finding on biopsy. Both atypical lobular hyperplasia and lobular in-situ neoplasia increase the risk for development of invasive carcinoma (four- and 10-fold, respectively). Subsequent invasive carcinoma after atypical lobular hyperplasia is three times more likely to occur in the ipsilateral breast (Page et al 2003). Carcinoma may arise 15–20 years after the initial diagnosis. The risk of developing subsequent invasive carcinoma after a diagnosis of lobular in-situ neoplasia is similar in both the ipsilateral and contralateral breasts.

Columnar cell lesions

Columnar cell lesions can be classified as either columnar cell change or columnar cell hyperplasia with or without atypia (Schnitt and Vincent-Salomon 2003). Atypical columnar cell lesions (also called flat epithelial atypia, blunt duct adenosis, columnar alteration of lobules, hypersecretory hyperplasia with atypia, pretubular hyperplasia, and columnar alteration with prominent snouts and secretions) have a low local recurrence rate and a low risk of progressing to invasive carcinoma. Some columnar cell lesions may represent a precursor of low-grade DCIS or invasive carcinoma, especially tubular carcinoma (Schnitt 2003). Columnar cell lesions diagnosed by needle core biopsy are advisedly excised to exclude in-situ or invasive cancer. Close follow-up of the patient is advised following excision (Nasser 2004). The radiological features of radial scars can mimic carcinomas, and the role of FNAC in diagnosis is limited. As malignancy cannot be excluded following needle core biopsy, excision biopsy of these lesions is advised.

Complex sclerosing lesion and radial scar

Stromal involution can produce areas of fibrosis. Radial scars are benign pseudoinfiltrative lesions of unknown significance, characterized by a fibroelastic core with entrapped ducts surrounded by radiating ducts and lobules showing variable epithelial hyperplasia, adenosis duct ectasia and papillomatosis. Radial scars and 'complex sclerosing lesions' (CSL) are usually asymptomatic and discovered through mammographic screening, but may present as a palpable

mass. The term 'radial scar' has been used for lesions measuring less than 1 cm, whereas CSL is reserved for those lesions over 1 cm in size (Kennedy et al 2003, Patterson et al 2004). Radial scars have been shown to be associated with BBD and a doubling of the risk of developing breast cancer (Nielsen et al 1987, Jacobs et al 1999). This risk is increased in women with larger and/or multiple radial scars.

Proliferative Stromal Lesions

Diabetic fibrous mastopathy

This is a rare form of lymphocytic mastitis and stromal fibrosis which can occur in patients with longstanding type 1 diabetes who have severe diabetic microvascular complications. It occurs in premenopausal women and, rarely, in men. It is known as 'diabetic mastopathy' or sclerosing lymphocytic lobulitis which does not predispose to breast carcinoma or lymphoma (Kudva et al 2003). Clinically, it is characterized by solitary or multiple ill-defined, painless, immobile, discrete lesions in one or both breasts. Mammographic and sonographic findings of these lesions are very suspicious for carcinoma; therefore, needle core biopsy is essential for diagnosis (Camuto et al 2000, Haj et al 2004). The pathogenesis of diabetic mastopathy is unknown, but it is thought to be an immune reaction to the abnormal accumulation of altered extracellular matrix in the breast, which occurs to connective tissue following hyperglycaemia (Haj et al 2004, Baratelli and Riva 2005). Annual follow-up is recommended in patients with diabetic fibrous mastopathy.

Pseudoangiomatous stromal hyperplasia of the breast

Pseudoangiomatous stromal hyperplasia (PASH) is a benign myofibroblastic proliferation of non-specialized mammary stroma. Clinicopathologically, it ranges from incidental, microscopic foci to mammographic and clinically palpable breast masses (Castro et al 2002, Guray and Sahin 2006). PASH is more common in premenopausal women and older women taking hormone replacement therapy; as a result, it was thought to be due to hormone stimulation, particularly progesterone. More recent studies have shown that only a small percentage of patients with PASH express either the oestrogen or progesterone receptor (Pruthi et al 2001, Castro et al 2002). PASH may present clinically as a well-circumscribed, dense rubbery mass mimicking a fibroadenoma or PT. As the mammographic and sonographic findings of PASH are non-specific, a needle core biopsy is required to exclude malignancy (Pruthi et al 2001, Mercado et al 2004). Wide local excision is the recommended treatment for PASH. It may recur but the prognosis is good (Castro et al 2002).

Breast Disorders Related to Pregnancy and Lactation

Pregnancy and lactation induce notable changes to the breasts in response to hormonal stimulation. Most of the tumours and disorders affecting the breasts are the same in pregnant/lactating women as in women who are not preg-

nant; however, some are unique to pregnancy and lactation. The majority of disorders related to pregnancy and lactation are benign, but pregnancy-associated breast cancer accounts for approximately 3% of all breast malignancies. All breast masses discovered during pregnancy and lactation require careful evaluation.

Lactogenesis

During pregnancy, the breast undergoes a number of changes in response to an increase in circulating hormones (oestrogen, progesterone and prolactin) beginning in the second month of the first trimester. Lactogenesis is a series of cellular changes whereby mammary epithelial cells are converted from a non-secretory state to a secretory state. This process is normally associated with the end of pregnancy and around the time of parturition.

Ultrasound is the most appropriate radiological investigation to evaluate breast disorders in women during pregnancy and lactation. The use of magnetic resonance imaging in the evaluation and treatment of pregnant women should be avoided, and only used where the risk:benefit ratio is clear (Talele et al 2003, Espinosa et al 2005). There is no conclusive evidence that magnetic resonance imaging has a toxic effect on the developing embryo, and the use of gadolinium-based contrast during pregnancy is probably safe as the quantity of gadolinium crossing the placenta is low and is rapidly excreted by the kidneys (Nagayama et al 2002, De Wilde et al 2005, Webb et al 2005). The use of mammography during pregnancy remains controversial, but it should be performed if malignancy is suspected as it is particularly effective in detection of microcalcifications and subtle areas of distortion, which may not be detected on ultrasound. The impact of prenatal exposure to ionizing radiation depends on three factors: the stage of fetal development at the time of exposure, the anatomical distribution of the radiation and the radiation dose. The fetus is most susceptible to radiation-induced malformations in the first 2 months of pregnancy (organogenesis). These malformations are believed to occur with exposure to more than 0.005 Gy of radiation (Greskovich and Macklis 2000). Two-view mammography of each breast performed with abdominal shielding exposes the fetus to 0.004 Gy of radiation; therefore, mammography with abdominal shielding can be performed should it be required during pregnancy. Recommendations are to avoid mammography in the first trimester; ultrasonography is preferable (Osei and Faulkner 1999, Sabate et al 2007).

Gestational and secretory hyperplasia

Microcalcifications following pregnancy or lactation are detectable by mammography, and it is important to distinguish these from pregnancy-like hyperplasia which manifests with similar findings in non-pregnant, non-lactating women (Sabate et al 2007).

Bloody spontaneous nipple discharge

This is an uncommon condition during pregnancy and lactation, but does occasionally occur in the third trimester when the vascularity of the breast is increased and changes in the

epithelium are more marked. Bloody spontaneous nipple discharge usually resolves with nursing, but can persist in severe cases. Nipple discharge is an uncommon symptom of pregnancy-associated breast cancer, but carcinoma must be excluded (Kline and Lash 1964, O'Callaghan 1981, Lafreniere 1990).

Galactocele

Galactoceles are the most common benign lesions in lactating women; however, they actually occur more frequently following cessation of breast feeding when the milk is retained (Scott-Conner 1997, Son et al 2006). Galactoceles are cuboidal or flat epithelium-lined cysts containing fluid resembling milk and inflammatory debris (Figure 46.5). The cysts form as a result of duct dilatation, and aspiration of the cyst is both therapeutic and diagnostic, producing milk during lactation and a more thickened milky fluid after lactation has ceased (Gomez et al 1986). Infection remains a common complication of galactoceles, and is easily confirmed with fine needle aspiration by a mixed purulent-milky material (Sabate et al 2007).

Pseudolipoma

Pseudolipoma occurs when the fat content of the breast is very high, and is a radiolucent mass.

Pseudohamartoma

Pseudohamartoma occurs when galactoceles contain variable proportions of old milk and water. The mass resembles a hamartoma as the high viscosity of old milk does not allow the separation of milk and water (Gomez et al 1986).

Gigantomastia

Gestational gigantomastia complicates between 1:28,000 and 1:118,000 deliveries (Lewison et al 1960, Beischer et al 1989). Gestational gigantomastia is a common phenotypic outcome from one or more aberrant growth-related pathways resulting in massive breast enlargement (Swelstad et al 2006). The diagnosis is one of exclusion. Medical management is usually ineffective but remains first-line therapy in the hope of avoiding surgery during pregnancy. Bromocriptine is the most common medical regimen, resulting in mild regression or arrest in breast hypertrophy. Effects are variable, usually temporary and do not restore breast volume to normal. If the quality of a woman's life suffers significantly or endangers fetal viability, surgical management (reduction mammoplasty or simple mastectomy) should be utilized (Swelstad et al 2006). Bilateral mastectomy with delayed reconstruction provides the smallest risk of recurrence should the woman become pregnant again (Wolf et al 1995, Swelstad et al 2006).

Puerperal mastitis

Infection of the breast is uncommon during pregnancy, but affects between 5% and 33% of women at some point during lactation (World Health Organization 2000). A study following up 1075 breastfeeding women in Australia reported

a 20% incidence of mastitis (Kinlay et al 1998). The wide variation in rates is probably because there is no standard definition of mastitis. The clinical spectrum of lactational mastitis (an acute inflammation of the interlobular connective tissue within the mammary gland, which may or may not be infective) ranges from focal inflammation to abscess with septicaemia. It most commonly develops in the early stages of feeding, with 74–95% of cases observed within the first 3 months of breast feeding (Devereux 1970, Marshall et al 1975, Foxman et al 2002). Cases have been reported as long as the woman is breast feeding. Three studies of breast-feeding women reported recurrent episodes of mastitis in 4–14.4% of cases (Fetherston 1997, Vogel et al 1999, Foxman et al 2002).

Mastitis is diagnosed on clinical symptoms and signs, and patients often present with pain, erythema and swelling. This can spread to affect the whole breast, with the patient becoming septic. It is usually unilateral and rarely presents at weaning. Breast examination often reveals oedema, erythema in a wedge-shaped distribution and tenderness (Bedinghaus 1997). If an abscess is present, a fluctuant mass may be palpable with overlying erythema. There are a number of predisposing factors for developing lactational mastitis including milk stasis [insufficient drainage of the breast, rapid weaning, oversupply of milk, pressure on breast (e.g. from poorly fitting bra)], a blocked duct and skin breakdown of the nipple (e.g. fissure, cracks or blisters). Infections developing within the first few months are often due to organisms transmitted in hospital, and are therefore resistant to most commonly used antibiotics. One study has demonstrated that in the first month of breast feeding, more than half of women have nipples colonized with *Staphylococcus aureus* (Livingstone and Stringer 1999). Eczema is a risk factor for infection, as women with eczema are more likely to harbour *S. aureus* (Noble 1998, Amir 2002). Additional risk factors for colonization with methicillin-resistant *S. aureus* include caesarean birth, administration of antibiotics during labour or the early postpartum period, and multiple gestations (Morel et al 2002). Another potential risk factor is in-vitro fertilization, which requires mothers to return to hospital on numerous occasions. Maternal stress, fatigue, poor nutrition, and maternal or infant illness have been associated with mastitis, although the evidence is inconclusive.

When infectious mastitis does occur, the organisms most often cultured from breast milk include *S. aureus* and coagulase-negative staphylococci (Lawrence 2005). Streptococcal infection should be suspected whenever bilateral mastitis presents in the postpartum period (Mead 1992). Delayed care or inadequate treatment can lead to abscess formation. Breast abscess is seen in 0.4–0.5% of lactating women, rarely occurring after the first 6 weeks of lactation. A 2004 study of more than 1000 women showed that 3% of women with breast inflammation will develop an abscess (Amir et al 2004). Abscesses can result in a functional mastectomy (defined as a breast that is unable to effectively lactate) in 10% of women (World Health Organization 2000). Ultrasound plays an important role in the diagnosis and treatment of mastitis if abscess formation is suspected. Abscesses can be treated successfully with needle aspiration to dryness under ultrasound guidance. The cavity is often irrigated with local anaesthetic to reduce pain followed by saline solution

Figure 46.5 Galactoceles can range from echo-poor (A) to echogenic (B) with variations in between, such as a layering of echogenic contents (C, arrowheads) or even apparent solid areas (D). The open arrow points to a small area of cream which was mobile within the galactocoele; aspiration confirmed its nature.

(Karstrup et al 1993, Ulitzsch et al 2004, Eryilmaz et al 2005).

The primary goal of treatment is to facilitate recovery and prevent complications. There is a consensus that lactation should be continued, allowing proper drainage of the breast. Early exclusive breast feeding (eight to 12 times per day) will

reduce the risk of milk stasis and maintain adequate drainage. Regular and frequent drainage of the breast, either by the infant, hand expression and/or pumping, is vital. Correct positioning of the infant and an assessment of infant latching and sucking is necessary. Close attention to regular drainage of the breast is important, even if the mother is

extremely unwell or the milk is contaminated. If direct breast feeding is not possible, regular bilateral pumping should be done with a hospital grade pump eight to 12 times per day for 15–20 min. Mothers require a lot of encouragement and emotional support to maintain breast feeding. As an adjunct to milk removal, a hot compress and gentle massage can also be used.

Promoting milk flow by continuing to breast feed from both breasts and the early use of appropriate antibiotics markedly reduces the rate of abscess formation. Culture of the milk organisms should ideally be performed before any antibiotics are commenced. Co-amoxiclav or flucloxacillin are the antibiotics of choice, or cephalixin and clindamycin in women allergic to penicillin. Tetracycline or ciprofloxacin should not be used in breastfeeding mothers as these medications enter the breast milk and may be harmful to the newborn child. Although there is no standard treatment length, a course of 10–14 days is often advised. Recurrent infective mastitis should be treated with antibiotics for no less than 14 days. Should recurrences occur two or three times in the same place, the breast should be further evaluated for an underlying aetiology such as a breast mass.

A number of complementary therapies for puerperal mastitis are available. These include herbal homeopathic options such as high-potency belladonna, Hepar sulph, *Bellis perennis* and *Phytolacca* (Barbosa-Cesnik et al 2003, Kvist et al 2007a). Midwives in Sweden use acupuncture needles placed at the heart 3, gallbladder 21, and spleen 6 (Kvist et al 2007b). They also use oxytocin nasal spray to improve the milk ejection reflex, which may have become distended from milk stasis (Kvist et al 2007).

Associated conditions include:

- Blocked ducts — usually present as hard lumps and can be an underlying aetiology of mastitis. Prevention of milk stasis is important, with other treatments including hot compresses and gentle massage over the blocked area. Recurrent blocked ducts may be prevented by manually expressing milk before feeding, limiting saturated fat intake, allowing for adequate rest and using a well-fitted bra.
- Nipple blebs — commonly associated with blocked ducts and manifest as a white spot on the nipple. They are treated by opening the pore with a sterile needle (Lawrence 2005). A galactoele may develop from a blocked duct, and infection should be suspected (particularly with *Candida* spp.) if the blocked ducts are persistent.
- Ductal infections — women often complain of a deep burning, aching or shooting pain in the breast during and after feeding (Amir and Pakula 1991). Should the nipple become involved, the mother may complain of itching. *S. aureus* and *Candida albicans* are the most commonly involved pathogens (Amir and Pakula 1991).

Non-Lactational Infections

These infections can be grouped into peripheral or periareolar. Periareolar infections are seen in young women, and are often secondary to periductal mastitis (associated with

cigarette smoking) (Schafer et al 1988, Bundred et al 1993). It is thought that particulates in cigarette smoke may indirectly or directly damage the wall of the subareolar ducts. Metabolites such as epoxides, nicotine, cotinine and lipid peroxidase have been shown to accumulate in smokers within 15 min of a woman starting to breast feed (Petrakis et al 1980). Smoking may affect normal bacterial flora, leading to a proliferation of pathogenic aerobic and anaerobic Gram-negative bacteria. Microvascular changes may also lead to local ischaemia. Patients with periareolar inflammation often present with a mass. Very rarely, the infection is due to underlying comedo necrosis in DCIS. It is advisable to perform a mammogram for all women over 35 years of age after resolution of the inflammation. The rate of recurrence is high for periareolar infections. Peripheral non-lactational breast abscesses are three times more common in premenopausal women than peri-/postmenopausal women. Some of these infections are most commonly caused by *S. aureus* and may be associated with diabetes, rheumatoid arthritis, exogenous steroid use and trauma.

All breast infections are treated with broad-spectrum antibiotics and clinical/ultrasound-guided drainage of any collections of pus (Hayes et al 1991). Aspiration has now become the standard of treatment superseding open drainage (Dixon 1988, 1992, O'Hara et al 1996). Patients should be reviewed every 2–3 days and any further collections aspirated. Periareolar non-lactational abscesses can be treated by repeated aspiration; however, persistent abscesses are common. Mammary duct fistula occurs in one-third of patients following incision and drainage of periareolar abscesses (Bundred et al 1987). These are definitively managed by excising the entire fistula tract with primary closure and antibiotic cover. Laying open of a mammary fistula leaves an unsightly scar across the nipple.

HIV infections

Immunocompromised patients (men and women) are particularly susceptible to breast infections.

Hidradenitis suppurativa

Hidradenitis suppurativa is an infection associated with the apocrine glands, affecting the axilla, perineum and breast. It is increasingly common in smokers, and treatment in the acute setting is as discussed above. Excision of the affected area with or without skin grafting is effective in 50% of patients.

Granulomatous mastitis

Granulomatous mastitis is a rare condition characterized by non-caseating granulomas and microabscesses confined to a breast lobule. Patients may present with recurrent/multiple abscesses or a hard, tender mass. Granulomatous mastitis occurs most commonly in parous, young women. Many different organisms can cause granulomatous mastitis, but a recent study isolated corynebacteria in nine out of 12 women with the condition (Erhan et al 2000, Paviour et al 2002, Diesing et al 2004). This condition is treated with broad-spectrum antibiotics.

Tuberculosis of the breast

Tuberculous mastitis is a rare breast condition in which the clinical and radiological features can be easily confused with carcinoma or pyogenic breast abscess. Diagnosis is based on identification of typical histological features under microscopy or the detection of tubercle bacilli (Tewari and Shukla 2005).

Foreign body reactions

Silicone and paraffin, both used in breast augmentation and reconstructive surgery, can cause a granulomatous reaction in the breast. Silicone granulomas (siliconomas) usually occur following direct injection of silicone into the breast tissue or following an extracapsular rupture of a silicone implant (van Diest et al 1998). Fibrosis and contraction may lead to the development of firm, tender nodules in the breast.

Recurring subareolar abscess (Zuska's disease)

This is a rare bacterial infection characterized by a triad of: (1) draining cutaneous fistula, (2) chronic, thick discharge from the nipple, and (3) recurrent mammary abscess (Passaro et al 1994). This is caused by squamous metaplasia of one or more lactiferous ducts, often induced by smoking. Keratin plugs obstruct and dilate the proximal duct, resulting in infection and rupture. An abscess may form which requires complete excision of the affected duct and the sinus tract for successful treatment.

Mastitis of infancy

During the last few uterine weeks, the fetus is subject to stimulation by placental and maternal hormones. Physiological hypertrophy of the breasts is a common feature in full-term neonates. On occasion, the swelling is more marked and may be accompanied by discharge from the nipple ('witch's milk'). The breast enlargement declines completely and the discharge resolves spontaneously. Occasionally, infants can present with a tender, erythematous breast mass accompanied by fever that requires intervention. Mastitis in early infancy is a rare, infectious complication of an otherwise physiological feature of postnatal breast hypertrophy.

Peak occurrence is reported between the second and fifth weeks of life (Rudoy and Nelson 1975, Walsh and McIntosh 1986, Efrat et al 1995, Stricker et al 2005). Females are more often involved than males (ratio 3.5:1). A possible explanation for the predominance of females is the tendency of breast hypertrophy in female newborns to persist longer than in males. The majority of cases are caused by *S. aureus*. The choice of antibiotic should be guided by Gram stain when possible, and otherwise should consist of an agent effective against *S. aureus* which is responsible for most cases. All patients require close monitoring for progression, and whilst there is no optimal duration of treatment, one study required treatment of patients for no longer than 14 days. In the case of abscess formation, incision and drainage under general anaesthetic combined with antibiotics is indicated.

Benign Neoplasms of the Breast

Adenoma

Adenoma is a pure epithelial neoplasm of the breast, and is subdivided into tubular, lactating, apocrine, ductal and pleomorphic adenomas. Lactating and tubular adenomas are more common in women of reproductive age. Lactating adenoma is the most common breast mass during pregnancy and puerperium, presenting as a solitary/multiple, discrete, palpable mobile mass, often less than 3 cm in size. The lesion is well circumscribed and lobulated, and acini are lined with actively secreting cuboidal cells. Lactating adenoma can occur in areas such as the axilla, chest wall or vulva (Reeves and Tabuenca 2000, Baker et al 2001). The tumour does not generally recur locally and there is no evidence of malignant potential.

Tubular adenoma of the breast (pure adenoma) presents as a solitary, well-circumscribed, firm mass. Radiologically, it may resemble a calcified fibroadenoma (Soo et al 2000). Lactating and tubular adenomas can be distinguished from fibroadenomas by the presence of scant stroma in the former.

Nipple adenoma

Nipple adenoma is a benign tumour that can clinically mimic Paget's disease. It presents as a discrete, palpable tumour of the papilla of the nipple. Nipple erosion and discharge are usually observed. It is treated by excision biopsy, but recurrences have been reported in incompletely excised lesions (Montemarano et al 1995).

Hamartoma

Hamartoma is an uncommon lesion also known as a 'fibroadenolipoma', 'lipofibroadenoma' or 'adenolipoma', consisting of varying amounts of glandular, adipose and fibrous tissue. Clinically, a hamartoma may present as a painless, discrete encapsulated mass, and although the pathogenesis is not certain, it is thought to develop as a result of dysgenesis. Mammographically, it is well circumscribed, consisting of both lipomatous and soft tissue elements (Herbert et al 2002, Gatti et al 2005). Histologically, the appearance is of normal breast and fat tissue distributed in a nodular fashion within a fibrotic stroma that extends between individual lobules and destroys the normal interlobular specialized loose stroma (Tse et al 2002). Hamartomas are managed by surgical excision.

Lipoma

Lipoma of the breast is a benign, often solitary tumour composed of mature fat cells that tends to present in the fifth decade. Clinically, it may present as a well-circumscribed, smooth or lobulated mass that is soft and non-tender. Imaging shows a radiolucent mass on mammography and either normal or echogenic fat on ultrasonography (Figure 46.6), and FNAC often reveals fat cells with or without normal epithelial cells. If the diagnosis is uncertain, surgical excision is recommended (Lanng et al 2004). Liposarcoma of the breast is very rare (Blanchard et al 2003). Pseudolipoma of the breast may present clinically as a lipoma, but

is actually a small cancer that produces compressed fat lobules as the suspensory ligaments of the breast shorten.

Granular cell tumour

This is an uncommon benign tumour that arises from the Schwann cells of the peripheral nervous system. It occurs frequently in the head and neck (particularly the oral cavity), and occurs in the breast in 5–6% of cases (Montagnese et al 2004). Clinically and mammographically, it can mimic carcinoma (Ilvan et al 2005). These tumours are generally small (<3 cm) and well circumscribed; however, in some cases, infiltrative margins have been reported. S100 immunostaining supports the derivation of this tumour from Schwann cells (Balzan et al 2001). Most granular cell tumours are benign, but some malignant cases have been reported. Suspicious features for malignancy include size over 5 cm, cellular and nuclear pleomorphism, prominent nucleoli, increased mitotic activity, presence of necrosis and local recurrence

Figure 46.6 Lipoma. Note the subtle increase in echogenicity within the fat (arrow heads). The fibrous margins of the lipoma are only obvious where its capsule is near to right angles with the insinuating beam. The extended field to view image means that the capsule appears incomplete, but this is because the sound is only reflected when the capsule is at right angles to the insinuating beam.

Figure 46.7 (A) A normal lymph node which is almost isoechoic with the axillary tissues, which are a mixture of fat and connective tissue. The arrows point to the outer edges of the cortex, which is of reduced echogenicity. This is an approximate 'C' shape, with a central medullary area of increased echogenicity within the 'C' shape. (B) An abnormal lymph node in the axilla of the same patient. Arrows point to an area of reduced echogenicity which has loss of the normal corticomedullary differentiation. Although this is a smaller lymph node, fine needle aspiration confirmed the presence of tumour.

(Adeniran et al 2004). These tumours are treated with wide local excision, with incomplete margins resulting in local recurrence.

Other Breast Masses

Montgomery's glands

These are blind-ending ducts distributed throughout the areola which produce fluid to lubricate the areola during breast feeding. They were named after William Fetherstone Montgomery (1797–1859), an Irish obstetrician who was the first to describe them. These glands can become blocked, forming hard nodules on the periphery of the areola, which can occasionally become infected. The management of these prominent glands is reassurance unless the patient becomes symptomatic.

Fat necrosis

Fat necrosis is a benign non-suppurative inflammatory condition affecting the adipose tissue of the breast. It can occur secondary to trauma (accidental/surgical) or may be associated with carcinoma, duct ectasia and fibrocystic disease. Clinically, it can mimic carcinoma if it appears as an ill-defined or dense speculated mass, associated with skin retraction (Kinoshita et al 2002). Imaging may not always be able to distinguish between fat necrosis and carcinoma (Pullyblank et al 2001). Excision biopsy is required if malignancy cannot be excluded on needle core biopsy.

Mondor's disease

This is spontaneous superficial thrombophlebitis of a breast vein. It is often painful, and clinically, there may be a thick palpable cord with associated erythema. The aetiology includes surgery, trauma and infection. It is a self-limiting condition that resolves in a couple of weeks.

Oil cysts

This benign condition can be identified mammographically if the cysts have a calcified rim or lie within parenchyma.

Within the fat, they often cannot be identified because of the lack of difference in density. On ultrasound, it may not be possible to differentiate oil cysts from ordinary cysts because they may be echo-free or contain echoes, and have an appearance similar to fluid-filled cysts. If there is an oil/water mixture, the fluid level is easily identified on ultrasound or mammography.

Sebaceous cysts

Sebaceous cysts are easily identified on ultrasound due to their position, the fact that they are well defined, and because the internal echoes are usually increased due to the lipid content.

Lymph nodes

Lymph nodes may be isoechoic with the surrounding fat in a mainly fatty breast. They usually have an oval shape, with a slightly more translucent cortex and a slightly increased echogenic medulla (Figure 46.7). The vessels entering the hilum of the cortex can frequently be demonstrated with the aid of colour Doppler. Reactive, hypertrophied lymph nodes retain their anatomical structure and appearance, whereas lymph nodes that have been invaded by the tumour from a breast primary are usually masses of reduced echogenicity, often with a similar echogenicity to the tumour. As in other parts of the body, it is not always possible to exclude the presence of tumour from a node which appears to be hypertrophied with a normal architecture.

KEY POINTS

1. If possible, imaging of the breast should precede FNAC or core biopsy to avoid difficulties in interpretation due to the changes caused by these procedures.
2. Ultrasound can now diagnose many benign lesions with a high degree of certainty, and is the imaging method of choice for women under 35 years of age.
3. Mammography is not recommended for women under 35 years of age except if it is required to evaluate a known carcinoma.
4. Cyclical breast pain is very common and 85% of patients are satisfied with explanation alone. The remainder may be treated with gamolenic acid, danazol, bromocriptine or tamoxifen.
5. Women with multiple breast cysts have an increased risk of breast cancer.
6. Approximately 5% of what are thought clinically to be fibroadenomas are, in fact, malignant. Investigation with ultrasound and fine needle aspiration or core biopsy is required.
7. Breast abscesses can usually be treated with repeated needle aspiration.

Introduction

Breast cancer is one of the most common malignancies afflicting women, and is the leading cause of cancer-related mortality (Hortobagyi et al 2005). Worldwide, more than 1.2 million women are diagnosed with breast cancer each year, affecting 10–12% of the female population and resulting in 500,000 deaths per year. In the UK in 2005, there were 45,947 new cases: 45,660 (over 99%) in women and 287 (<1%) in men, causing approximately 14,000 deaths per year (Information Statistics Division Online 2008, Office for National Statistics 2008, Northern Ireland Cancer Registry 2008, Welsh Cancer Intelligence and Surveillance Unit 2008). The lifetime risk of a woman being diagnosed with breast cancer is one in nine (Health Statistics Quarterly 1999, Information Statistics Division Online 2008, Welsh Cancer Intelligence and Surveillance Unit 2008). Whilst it is impossible to predict who will develop breast cancer, it is

possible to identify those women who are at increased risk for breast cancer and provide options for reducing the risk.

Trends in Breast Cancer Incidence and Prevalence

More than 80% of cases of breast cancer occur in women over 50 years of age, with the highest incidence in women aged 50–69 years. The incidence of breast cancer has been increasing for many years in economically developed countries. The UK age-standardized incidence of breast cancer per 100,000 women increased from 74 in 1975 to 123 in 2005 (Coleman 2000). The introduction of a national screening programme in the UK in 1988 led to a transient increase in breast cancer incidence in women aged 50–64 years, as early undiagnosed cancers were detected. This increase lasted for the first 4–7 years of the programme. However, an underlying increase in incidence predating screening continues

today and is particularly evident in older age groups. Mortality rates for breast cancer have fallen in many developed countries since 1990, having been previously stable/increasing for several decades (Beral et al 1995, Peto et al 2000, Jatoi and Miller 2003). This reduction has been attributed to earlier detection following the implementation of breast screening, decreased use of exogenous hormones and the use of adjuvant therapies such as tamoxifen (Berry et al 2005).

As the incidence of breast cancer is high and the 5-year survival rate is approximately 80%, many women are alive who have been diagnosed with breast cancer. An estimated 550,000 women are alive in the UK who have received a diagnosis of breast cancer (Maddams et al 2008).

Risk Factors

Many factors are associated with an increased risk of developing breast cancer; however, only 25% of women with a sporadic case of breast cancer will have an identifiable risk factor.

Age

Age is the single most important risk factor for the development of breast cancer (Colditz and Rosner 2000). The incidence of breast cancer increases with age, doubling every 10 years to the menopause, and then the rate of increase slows, levelling to a plateau after 80 years (Anderson et al 2005). This creates a point of inflection in the age-specific incidence curve known as 'Clemmensen's hook' (Clemmensen 1948). The incidence of oestrogen-receptor-alpha (ER α)-negative tumours rises rapidly to 50 years and then flattens out/decreases, whereas the incidence of ER α -positive tumours is similar up to the age of 50 years but then continues to increase, albeit at a slower pace. As a result, ER α -negative tumours tend to occur earlier in life and ER α -positive tumours are more common in older women. The peak age of onset for these two tumour phenotypes is 50 years and 70 years, respectively.

Ethnicity changes the effect of age on breast cancer risk. African-American women under 50 years of age have a higher age-specific incidence of breast cancer than their Caucasian counterparts (Vogel 1998). However, the incidence of breast cancer is higher in Caucasian women after 50 years of age. The difference in age-adjusted breast cancer mortality rates between African-American and Caucasian women in the 1980s was probably due to the greater incidence of ER α -negative tumours in African-American women, who will not have benefited from the introduction of adjuvant hormonal therapy (Jatoi et al 2005).

Geographical variation

Worldwide, more than 1 million women are diagnosed with breast cancer every year, accounting for 10% of all cancer cases and 23% of all female cancer cases (Ferlay et al 2004). Incidence rates for breast cancer are six times greater in the Western world than in underdeveloped countries. Approximately 430,000 new cases of breast cancer occur each year in Europe and an estimated 212,920 in the USA. The lowest rates in Europe are found in Romania and Latvia, and the

highest rates are found in Northern and Western Europe. The incidence of breast cancer in American Hispanic women is 40–50% that of non-Hispanic White women.

Migrants from low-risk countries to high-risk countries have been shown to acquire the risk of the 'host nation' within two generations (Tominaga 1985, Ziegler et al 1993). Japanese migrants to the USA acquire an increased breast cancer risk compared with the population in Japan, and there is increasing evidence that the earlier in life a woman takes up residence in a 'high-risk' country, the higher the risk of breast cancer compared with the country of origin (Shimizu et al 1991, Ziegler et al 1993).

Ovulatory cycles

Events in a woman's life that alter her lifetime ovulatory cycles appear to correlate with the risk of breast cancer. Women who start menstruating early or have a late menopause have a 30–50% increase in risk of developing breast cancer. Similarly, late menarche and an early menopause lead to an equivalent reduction in breast cancer risk. The risk of developing breast cancer is doubled in those women who have a natural menopause after 55 years of age compared with those who experience the menopause before 45 years of age. A menopause induced before 40 years of age reduces the risk of breast cancer by almost two-thirds (Hankinson et al 2004).

Age at first pregnancy

Late age at first birth and nulliparity increase the lifetime risk of breast cancer. Nulliparity has been a well-known risk factor for developing breast cancer since Ramazzini described *horrendis mammarium canceris* in Catholic nuns (Ramazzini 1713). The risk of breast cancer in women who have their first child after 30 years of age is double that of women who have their first child before 20 years of age. The group at highest risk are those women who have their first child after 35 years of age. These women have a greater risk than nulliparous women. An early age of birth of a second child confers a reduced risk. The protective effects of an early full-term pregnancy have been observed in a number of ethnic groups and geographic locations, suggesting that the parity-induced protection results from biological changes in the breast rather than environmental factors.

Benign breast disease

Prospective and retrospective studies have shown a relative risk of breast cancer of 1.5–1.6 for women with benign breast disease compared with the general population (Hartmann et al 2005). This increased risk has been shown to persist for 25 years after biopsy. The relative risk of proliferative changes with atypia was 4.24 compared with a relative risk of 1.88 for those without atypia and 1.27 for non-proliferative lesions. The age at diagnosis of the benign breast disease appears to modify the risks related to the histological appearance of benign breast disease. The presence of atypia in women under 45 years of age conveys twice the risk observed among women over 55 years of age. The Breast Cancer Detection and Demonstration Project showed that the risk of breast cancer among premenopausal women

with atypia was elevated by a factor of 12.0, compared with 3.3 for postmenopausal women with atypia (London et al 1992, Dupont et al 1993). An increase in breast cancers has been demonstrated in the same breast during the first 5 years of follow-up following a diagnosis of benign breast disease, particularly in women with atypia.

Ionizing radiation exposure

The understanding of radiation-related breast cancer in women derives from epidemiological studies of patients exposed to diagnostic or therapeutic medical radiation (mantle irradiation for lymphoma) and of the Japanese atomic bomb survivors (United Nations Scientific Committee on the Effects of Atomic Radiation 2000). The breast tissue of young women is highly sensitive to the carcinogenic action of ionizing radiation. Only the bone marrow and the infant thyroid gland are more sensitive to the cancer-causing effects of radiation. Ionizing radiation is an established breast cancer risk factor and this risk has been shown to increase linearly with dose. Age at exposure directly affects radiation-related breast cancer risk, with the greatest risk seen in women exposed before 20 years of age and a significantly reduced risk seen for postmenopausal women. Periods of enhanced cell proliferation, namely *in utero*, puberty and pregnancy, have been proposed to represent windows of increased susceptibility for mammary carcinogenesis (Ronckers et al 2005).

A two-view mammogram results in a breast tissue dose of approximately 0.3 cGy (annual exposure from all sources of natural 'background' radiation being approximately 0.1 cGy). Therefore, with a woman receiving 10 mammograms as a young woman, the total dose would be approximately 3 cGy to each breast. Bearing in mind that epidemiological studies have not detected statistically significant increases below a dose of approximately 20 cGy, and knowing that 100 cGy increases risk by approximately 40%, one can estimate that 3 cGy from periodic mammography screenings would increase the risk by approximately 1.2% or a relative risk of 1.012. Such low risks are not detectable in human studies. Nonetheless, all unnecessary radiation should be avoided and although the presumed risk is very small, it should be clear that the benefit from the medical exposure would far outweigh it.

Oral contraceptive pill

Use of the oral contraceptive pill slightly increases the risk of breast cancer in current and recent users (1–4 years following cessation) with relative risks of 1.24 and 1.16, respectively (Collaborative Group on Hormonal Factors in Breast Cancer 2002). This risk diminishes after discontinuing use and returns to normal after 10 years.

These estimates are based on the Collaborative Group on Hormonal Factors in Breast Cancer study; a collaborative meta-analysis of 54 studies in 25 countries with data on over 50,000 women with breast cancer (Anonymous 1996). Cancers diagnosed in women who have used the oral contraceptive pill tend to be less clinically advanced than those detected in women who have never used it. Users of the oral contraceptive pill are generally younger women whose breast cancer risk is comparatively low, so the small excess in

current users will result in a relatively small number of additional cases. Other findings of the study were:

- protective effect against benign breast disease;
- no duration-of-use effect, no pill-type effect and no effect of age at first use;
- no increased risk in women aged over 45 years; and
- the risk of using the oral contraceptive pill was similar regardless of a woman's family history, ethnic origin, age at menarche, height, weight, menopausal status and alcohol consumption.

A large case–controlled study of 4575 women aged 35–64 years showed that current or former use of the oral contraceptive pill was not associated with a significantly increased risk of breast cancer (Marchbanks et al 2002).

Hormone replacement therapy

Hormone replacement therapy (HRT) use increases the risk of breast cancer and reduces the sensitivity of mammography. The risk of breast cancer for current or recent users of HRT increases by 2.3% per year of use. For women who have used HRT for at least 5 years (average 11 years), the increased risk was 35% (Anonymous 1997a). The effect is substantially greater for oestrogen–progesterone combinations than for oestrogen-only HRT. Risk increases with duration of use; the risk for current users of oestrogen–progesterone combinations for more than 10 years was 2.31 compared with 1.74 for 1–4 years of use. Risk decreases with cessation of use; past users (>5 years following cessation) have a similar risk to those who have never taken HRT. One recent study reported that current users of combined HRT had a 2.7-fold elevated risk of lobular cancer and a 3.3-fold risk of ductal cancer. The risk of lobular cancer was only raised in women who had used HRT for 3 years or more.

In the UK over the past 10 years, it is estimated that 20,000 extra breast cancer cases have occurred among women aged 50–64 years as a result of HRT use, and three-quarters (15,000) of these additional breast cancers are due to the use of oestrogen–progesterone HRT. HRT is used by over 20 million women in Western countries for the alleviation of perimenopausal and postmenopausal symptoms, and is an important source of exogenous oestrogen and, in some cases, progesterone exposure. A recent review concluded that the excess incidence of breast cancer, stroke and pulmonary embolism in postmenopausal women who use HRT for 5 years was greater than the reduction in incidence of colorectal cancer and hip fracture (Beral et al 2002). The risks and benefits for treating menopausal symptoms should be evaluated on an individual basis.

A decrease in the incidence of breast cancer among postmenopausal women in the UK may be linked to a decrease in the use of HRT. Researchers calculated that between 1999 and 2005, the risk of the disease fell by 14% in women in their 50s, representing 1400 fewer cases in 2005, and 3300 fewer over the period (Parkin 2009). They suggest that the decrease in breast cancer since 1999 in women aged 50–59 years and since 2003 in women aged 60–64 years is a consequence of the reduced use of HRT. The use of HRT began to fall after the Million Women Study in the UK and the Women's Health Initiative Study in the USA showed that HRT could increase the risk of breast cancer. In women aged

45–69 years, the use of HRT increased from 1992 to reach a peak of 25% in 2000–2001, before falling to approximately half that by 2006.

Hormone therapy after breast cancer is becoming an increasingly relevant problem as more women survive breast cancer. The HABITS (Hormonal Replacement Therapy After Breast Cancer — Is It Safe?) trial was designed to confirm the efficacy of HRT given to women after treatment for breast cancer (Holmberg and Anderson 2004). The trial confirmed an unacceptably high risk in women allocated to receive HRT compared with those receiving best symptomatic treatment, and as a result was terminated. Analysis of women in the HABITS trial after a median follow-up of 4 years showed that 17.6% in the HRT treatment arm had developed breast cancer recurrence or a new breast cancer, compared with 7.7% in the control arm. The estimated 5-year cumulative rate for disease recurrence was 22.2% in the HRT arm and 9.5% in the control arm.

Endogenous hormones

Higher levels of endogenous hormones have been hypothesized to increase breast cancer risk. A pooled analysis of nine prospective cohort studies found a statistically significant increased risk of breast cancer in postmenopausal women with higher levels of sex hormones (Key et al 2002). The risk for women whose oestradiol levels were in the top quintile was approximately twice that compared with women whose oestradiol levels were in the bottom quintile. Evidence in premenopausal women was inconclusive.

Body weight

Increased weight and obesity, as measured by high body mass index (BMI), has been shown to moderately increase the risk of postmenopausal breast cancer and is one of the few modifiable risk factors. It is thought that between 7% and 15% of breast cancers in developed countries may be attributable to obesity. Two large studies — the EPIC study (European Prospective Investigation into Cancer and Nutrition) and the Million Women Study — have found that obese women have a 30% higher risk of postmenopausal breast cancer than women of a healthy weight. That means that if the average lifetime risk of breast cancer is one in nine, an obese woman's lifetime risk is one in seven. An increase in weight over time can also increase the risk of breast cancer.

Diet

A high-fat diet has been positively associated with breast cancer in a number of animal and case-control studies. Pooled analysis of cohort studies found no significant association between fat intake and breast cancer risk, whilst a meta-analysis found an association between higher total and saturated fat intake and an increased risk of breast cancer. A recent prospective study confirmed a significant association between saturated fat and breast cancer risk (Bingham et al 2003).

Alcohol intake

A significant association between alcohol intake and breast cancer has been found, with an increased risk of 7% for each

10 g alcohol/day (Hamajima et al 2002, Baan et al 2007). Approximately 4% of breast cancers in women from developed countries may be attributable to alcohol. In a recent large cohort of middle-aged women in the UK, a population with low-to-moderate alcohol consumption [10 g alcohol (one drink)/day] has shown a statistically increased risk of breast cancer; they also showed an increase in cancers of the oral cavity, pharynx, oesophagus, larynx, rectum and liver (Allen et al 2009). They calculated that the increased risk accounted for an additional 11 breast cancers per 1000 women up to 75 years of age. Although alcohol and tobacco are closely related social habits, there is no direct association between tobacco and breast cancer.

Height

Taller women have an increased risk of breast cancer (Hunter and Willett 1993). A pooled analysis estimated that the relative risk for women over 1.75 m tall compared with women under 1.6 m tall was 1.22 for all women and 1.28 for postmenopausal women (van den Brandt et al 2000).

Physical activity

A report from the International Agency for Research on Cancer concluded that physical activity has a preventive effect on breast cancer. This may be an indirect effect as exercise lowers BMI, or a direct effect on hormonal and growth factor levels. This varies between studies, with one showing a 30–40% reduction in the risk of breast cancer with a few hours of vigorous activity per week versus none (Monninkhof et al 2007).

Socioeconomic status

Breast cancer has a higher incidence in higher social classes. The age-standardized incidence rate is 115.1 per 100,000 women in the least deprived quintile compared with 97.3 per 100,000 women in the most deprived quintile. This is likely to be a reflection of other factors including reproductive history and early nutritional intake.

Mammographic density

There is extensive evidence that mammographic density is a risk factor for breast cancer, independent of other risk factors, and is associated with large relative and attributable risks for the disease. Women with increasingly dense breasts have two to six times the risk of breast cancer compared with women with less dense breasts (Boyd et al 1995). Parity, menopause and other risk factors only explain 20–30% of the variance in mammographic density (Boyd et al 2002). Early studies of mother-daughter sets and small twin studies suggested that genetic factors might explain a proportion of the variation of breast tissue patterns within a given population (Boyd et al 2002, Stone et al 2006). The genetic factors that influence mammographic density may also explain variations in breast tissue involution.

Previous history of breast cancer

If a woman has had breast cancer previously, the risk of developing a second primary breast cancer is two to six times

greater compared with the the risk of the general population of developing a primary breast cancer (Chen and Thompson 1999).

Family history

A family history of breast cancer, particularly in first-degree relatives, is a well-known risk factor for the development of breast cancer. The past few years have seen a significant increase in knowledge of inherited breast cancer. Approximately 80% of breast cancers are sporadic, and the other 20% are familial, occurring within the context of a positive family history. Twin studies have shown that inherited factors may account for up to 25–30% of all breast cancers (Laloo et al 2003). These cancers are the result of a combination of genetic and environmental factors that cause acquired genetic mutations over time (Vogel and Bevers 2003). A woman with one first-degree relative has approximately double the risk of breast cancer of a woman with no family history of the disease. The risk is greater if two (or more) relatives are affected. Multiple primary cancers in one individual or related early-onset cancers in a family pedigree are highly suggestive of a predisposing gene.

The first two major susceptibility genes for breast cancer, *BRCA1* and *BRCA2*, were identified in 1994 and 1995, respectively. Mutations and genomic rearrangements within the *BRCA1* and *BRCA2* genes have been clearly associated with breast cancer. The inherited mutation of these genes represents the first hit of Knudson's two-hit model of tumorigenesis. *BRCA* gene mutations interfere with the DNA-repair function of the normal gene, resulting in the accumulation of chromosomal abnormalities and an increased susceptibility to develop malignancy.

BRCA1 and *BRCA2* account for the largest proportion of familial breast cancer cases. It is thought that 20–25% of familial breast cancer cases are due to mutations or genomic rearrangements within these genes. The frequency of these mutations is rare, occurring in 0.1–0.5% of the general population, compared with 2% in Ashkenazi Jews (Rebbeck et al 2002). The breast cancer risk attributable to *BRCA1* and *BRCA2* mutations in Ashkenazi Jews is as high as 15–30% (FitzGerald et al 1996, Abeliovich et al 1997, Struewing et al 1997, Metcalfe et al 2004). A recent analysis of 22 studies showed that carrying a deleterious *BRCA1* or *BRCA2* mutation confers an estimated lifetime risk for developing breast cancer of 65% and 45%, respectively (Antoniou et al 2003). By the age of 40 years, carrying a deleterious *BRCA1* mutation confers a 20% chance of developing breast cancer, and the risk increases with age (Kauff et al 2002). Mutations in *BRCA1* are strongly associated with ovarian and fallopian tube cancers (Antoniou et al 2003). The risk of ovarian carcinoma for *BRCA1* carriers is 17%, 39% and 54% at 40, 70 and 80 years, respectively (Antoniou et al 2003). Penetrance of *BRCA1* with respect to ovarian, fallopian and breast cancer is greater than that for *BRCA2*.

Tumours associated with *BRCA1* carriers are more frequently grade 3, and ER α -negative and ovarian carcinomas, which occur in *BRCA1/2* families, are mostly non-mucinous epithelial cancers (Lakhani et al 2002). No single technique is able to detect all mutations, and even by sequencing the entire gene, the detection rate is only 85% (Evans et al 2003). Once a mutation has been identified in a family, definitive genetic testing can inform women more accurately

of their risks and give them an informed choice of their options. Mutational analysis of an unaffected individual is problematic without checking an affected relative. Identification of a mutation will confirm an increased risk; however, the absence of a mutation does not exclude the possibility of a refractory mutation of another gene. Where there is not a dominant family history or a *BRCA1/2* mutation is not identified, risk estimation gives a 1.5–3 fold relative risk with a family history of a single first-degree relative affected (Newman et al 1988, Claus et al 1994).

Quantitative Risk Assessment

A number of models are available to calculate a woman's risk of developing breast cancer. These utilize different combinations of risk factors derived from different data sets, and vary in the age to which they calculate cumulative risk of breast cancer. As a result, they may generate different risk estimates for a given patient.

The Gail model

The Gail model quantifies a woman's lifetime risk of developing breast cancer by incorporating patient age, age at menarche, age at first birth/nulliparity, number of breast biopsies, ethnic origin and history of breast cancer in first-degree relatives (Gail et al 1989, Costantino et al 1999). It does not, however, consider the ages of first-degree relatives with breast cancer, and overlooks a family history of bilateral breast disease, second-degree relatives with breast cancer and a family history of ovarian cancer. Also, the model does not account for a personal history of atypical hyperplasia and lobular carcinoma *in situ*, previous radiation therapy to the chest for the treatment of Hodgkin's lymphoma, or recent migration from a region of low breast cancer risk (e.g. rural China) to a high-risk region. The Gail model remains the most frequently used in defining eligibility for risk reduction trials.

The Claus model

The Claus model provides breast cancer risk estimates based on which relatives were diagnosed with breast cancer and at what age their diagnosis was made. Initially, only data from mothers and sisters were included, but second-degree relatives were included subsequently (Claus et al 1994).

BRCAPRO

BRCAPRO was developed by statisticians at Duke University to calculate age-specific probabilities of developing breast and ovarian cancer, based on the probability that the individual carries a mutation on one of the *BRCA* genes (Berry et al 1997). The model uses the observed incidences of breast and ovarian cancer among *BRCA* gene mutation carriers and non-carriers to calculate the probability that a given individual is a mutation carrier based on his/her family history.

The Tyrer–Cuzick model

The Tyrer–Cuzick model identifies the risk of breast cancer in unaffected women by taking into account their

probability of carrying genetic risk factors, namely a *BRCA1/BRCA2* mutation; a notional common, low-penetrance dominant susceptibility allele that stands for all other genetic risk factors; and a number of other individual factors known to influence risk, such as age at menopause and menarche, weight, height, age, use of HRT, previous benign breast biopsies and parity (Tyrer et al 2004).

Future developments

The Breast Cancer Prevention Collaborative Group has advised that the following risk factors should be further examined by multivariate analysis in future studies: mammographic density, plasma hormone levels, bone density and fracture history, history of weight gain, BMI and hip-waist ratio (Santen et al 2007). It is thought that the addition of these risk factors will lead to a more accurate quantitative risk assessment model for use in future breast cancer prevention trials. Whilst breast cancer risk assessment using mathematical models based on epidemiological data is valid, no one model integrates benign breast disease, oestrogen exposure and family history in a comprehensive fashion. Therefore, it is important to use a variety of models in a specialized risk assessment clinic.

Screening, Genetic Testing and Risk Reduction

Identification of candidates for genetic counselling and genetic testing remains important as only a small fraction of the estimated carriers have been identified. There is growing evidence that high-penetrance germline mutations in genes such as *BRCA1* and *BRCA2* account for a small proportion of familial risk of breast cancer, and the majority of the remaining risk is likely to be caused by combinations of more common, lower penetrance variants.

Breast cancer family history clinics are well established in the UK, and are run by medical oncologists, clinical geneticists, nurse specialists and breast surgeons in a multidisciplinary approach with close involvement of radiologists and psychologists (Evans et al 1994, 1996). After a risk assessment, women are divided into three risk groups: average, moderate and high risk. Patients should undergo pretest counselling to ensure understanding of the implications of a positive test. This should also include the risks and benefits of early cancer detection and the prevention modalities available. Counselling following testing should be available to help patients to cope with their test results and review prevention modalities. Once advised of their risk, women deciding to pursue risk reduction therapy can be presented with their management options.

Surgical management

Prophylactic/risk-reducing mastectomy (RRM) is an option for breast cancer risk reduction in high-risk women. The significant psychological and physical burden associated with RRM is reserved for those women whose lifetime risk of developing breast cancer is high. High-risk women are classified as those with a lifetime risk above 25%. This risk is the equivalent of having one first-degree relative with breast cancer diagnosed below the age of 50 years, or three affected relatives (first-degree) diagnosed under the age of

60 years. The efficacy of RRM is controversial and depends on the amount of residual tissue following the procedure. A retrospective study of 639 women with a family history of breast cancer suggests that RRM is associated with a 90% reduction in risk (Hartmann et al 1999). One small prospective study investigating the efficacy of prophylactic mastectomy in *BRCA1/2* carriers with a mean follow-up of 3 years showed that those women undergoing mastectomy had a significant reduction in the incidence of breast cancer (0 of 76 women) compared with the surveillance group (eight of 63 women) (Meijers-Heijboer et al 2001).

The use of RRM is increasing, with women often choosing to have breast reconstruction surgery either immediately or delayed. The timing of the reconstruction is controversial, with immediate reconstruction appropriate in the majority of women. It is now felt that the psychological benefit of emerging from a mastectomy with a breast mound far outweighs the need for a waiting period (Kronowitz 2007). The process from first consultation to surgery takes 6–12 months; this delay deliberately allows women enough time for the decision-making process.

Bilateral prophylactic oophorectomy

Studies have shown a significant reduction in the incidence of breast cancer in women with *BRCA1/2* mutations that have undergone prophylactic bilateral oophorectomy (Rebbeck et al 2002). Before undergoing the procedure, the patient should take into account how long she wishes to maintain her fertility, and should receive counselling about the risks and benefits of prophylactic oophorectomy. Opinion is divided on the use of HRT following prophylactic oophorectomy, with some centres routinely recommending HRT for all patients up to 50 years of age; the decision to use oestrogens should be based on a consideration of symptoms affecting future health and quality of life.

Chemoprevention

Chemoprevention provides a non-invasive option for breast cancer risk reduction for many high-risk women. Tamoxifen, a selective oestrogen receptor modulator (SERM) well known for its antioestrogenic effects in breast tissue, was the first agent used in breast cancer risk reduction after it was found to reduce the incidence of all breast cancers by 38% and ER-positive tumours by 48% (Cuzick et al 2003).

Pathology

The World Health Organization's classification of breast tumours organizes both benign and malignant lesions by histological pattern. Epithelial tumours comprise the largest group, including intraductal papilloma, adenomas, intraductal and lobular carcinoma *in situ*, invasive (ductal and lobular) carcinoma, and Paget's disease of the nipple. Invasive ductal carcinoma is by far the most common type.

In-situ carcinoma

These are preinvasive carcinomas. The proliferation of epithelial cells remains confined by an intact basement membrane, with no invasion into the surrounding stroma.

Ductal carcinoma *in situ*

Breast screening has resulted in a marked increase in the detection of ductal carcinoma *in situ* (DCIS), accounting for 25–30% of all screen-detected tumours (Schwartz et al 2000). Over 90% of DCIS is impalpable, asymptomatic and often detected by screening as microcalcifications (Figure 47.1). The remaining 10% are symptomatic, presenting with nipple discharge, a palpable mass or Paget's disease of the breast. When diagnosed clinically, DCIS is often extensive or associated with a concurrent invasive tumour. Postmortem studies have shown prevalence of DCIS from 0.2% to 14% (Bartow et al 1987, Nielsen et al 1987). Risk factors for DCIS include older age at first childbirth, nulliparity and a family history of breast cancer (Raktovich 2000). Retrospective studies of cases of low-grade DCIS misdiagnosed as benign showed that 20 years after local excision, approximately 33% had developed invasive disease (Page et al 1995). DCIS is classified into two major subtypes according to the presence/absence of comedo necrosis (atypical cells with abundant luminal necrosis that fill at least one duct) (Silverstein et al 1996). A system of low, intermediate and high nuclear grade is used to classify DCIS.

- Low-grade DCIS: evenly spaced cells with centrally placed small nuclei, few mitoses and the nucleoli are not well seen.
- High-grade DCIS: pleomorphic irregularly spaced cells, with large irregular nuclei, frequent mitoses and prominent nucleoli. Often solid with comedo necrosis and calcification.
- Intermediate-grade DCIS: features between high- and low-grade DCIS.

Figure 47.1 Ductal carcinoma *in situ*. Intermediate-grade ductal carcinoma *in situ* (DCIS) exhibiting classical comedo-type casting calcification within the ducts. The linear branching pattern is very typical of DCIS. Small arrows demonstrate the casting branching pattern of DCIS. The more density clustered area of calcification is associated with a local area of invasive ductal carcinoma (arrow head).

Most cases of DCIS are unicentric, with only 1% showing multicentric disease (Holland et al 1990b).

Multicentric tumour is defined as separate foci of tumour found in more than one breast quadrant or more than 5 cm from the primary tumour. Multifocal tumour is defined as more than one tumour foci in the same quadrant (Anonymous 1998c).

The spread of DCIS locally is along the branching ducts that form the glandular breast, and explains why most DCIS recurrences occur at or near the site of the initial tumour (Holland et al 1998). Micro-invasion is uncommon in DCIS, but confers a 2% risk of lymph node metastasis (van Dongen et al 1989). Studies have shown that poorly differentiated, high-grade comedo DCIS has low ER expression, high rates of cell proliferation, and overexpression of c-erbB2 (HER-2/neu) and epidermal growth factor receptor (EGFR) (Millis et al 1996). Low-grade lesions have high ER expression, lower rates of cell proliferation and rarely express HER-2 (Millis et al 1996, Bolland et al 2002). Small, localized areas of DCIS (<4 cm) should be treated with breast-conserving surgery (BCS) with or without radiotherapy, and larger lesions need to be treated with mastectomy (Schwartz et al 2000).

The incidence of macroscopic nodal involvement in DCIS is less than 1%; however, nodal micrometastases have been reported in 5–14% of patients (Schuh et al 1986, Kitchen et al 2000). Two small, single-institution studies have reported a 3.1% rate of sentinel lymph node involvement in 223 patients with pure DCIS. Sentinel lymph node biopsy (SNB) for DCIS is not currently indicated but is under investigation, and may have a role in mastectomy for DCIS (Intra et al 2003). SNB should only be considered in those patients with a higher likelihood of underlying, undetected invasive disease (i.e. younger patients, DCIS >4 cm, high-grade DCIS and patients undergoing mastectomy). Twenty-five percent of cases recur within 8 years of BCS alone, 50% of which will present with invasive disease (Fisher et al 1999, Julien et al 2000, Ottesen et al 2000, Chan et al 2001); the recurrence rate for DCIS following mastectomy is 1% (Silverstein et al 1995). The key factor for recurrence is a clear margin at the time of surgery, and poor prognostic indicators include younger age at diagnosis (<40 years), poorly differentiated/high-grade tumours, presence of comedo necrosis, ER negativity and HER-2 positivity (Yen et al 2005).

The NSABP-B17, EORTC 10853 and UK/ANZ DCIS trials evaluated the value of radiotherapy following BCS for DCIS (Fisher et al 1999, Julien et al 2000, Houghton et al 2003). All of the trials reported a significant reduction in ipsilateral recurrence following radiotherapy. The EORTC trial showed a reduction in recurrence of DCIS from 8% to 5%, and a reduction in invasive recurrence from 8% to 4% at 5 years.

Lobular in-situ neoplasia

Lobular in-situ neoplasia (LISN; formerly known as lobular carcinoma *in situ*) is not itself a premalignant lesion but is a high-risk marker of invasive cancer. It is often an incidental finding during breast biopsy, and accounts for 0.5% of symptomatic and 1% of screen-detected tumours. Patients with LISN are younger, premenopausal with bilateral and multicentric disease of lower grade. Almost all patients express ER (Akashi-Tanaka et al 2000). If LISN is detected

at core biopsy, the area should be subjected to excision biopsy to confirm the diagnosis and exclude an invasive focus. The NSABP P-1 prevention trial reported a 56% risk reduction of developing subsequent invasive cancer with tamoxifen in patients with a history of LISN (Dunn and Ford 2000).

Invasive carcinoma

Invasive ductal carcinoma

Approximately 80% of breast cancers are invasive (infiltrating) ductal carcinoma (IDC), not otherwise specified; a generic term used to distinguish between these tumours and other specific forms of ductal carcinoma, such as tubular, medullary, metaplastic and adenoid cystic carcinomas. IDC includes a subset of tumours that express, in part, characteristics of one of the specific types of breast carcinoma but do not constitute pure examples of the individual tumours. IDC invariably form a solid tumour, and cystic change in this group of lesions is extremely uncommon but may be a manifestation of necrosis.

Invasive lobular carcinoma

Invasive lobular carcinoma (ILC) is the second most common type of invasive breast cancer accounting for 8–14% of all invasive breast cancers (Arpino et al 2004). ILC clinically presents as a poorly defined thickening of the breast rather than a dominant mass. This makes the extent of the disease difficult to estimate on clinical examination, and difficult to visualize on mammography. Ultrasonography is more sensitive than mammography in detecting ILC, but may significantly underestimate the size of the lesions (Pritt et al 2004, Selinko et al 2004). Magnetic resonance imaging (MRI) is more accurate than either mammography or ultrasonography in defining the extent of the disease but is less widely available (Weinstein et al 2001). Due to the infiltrative growth pattern, there is a higher incidence of resection margin involvement than for IDC and a higher conversion rate to mastectomy (Yeatman et al 1995). ILC has a higher incidence of being bilateral, multifocal and multicentric than IDC (Figure 47.2) (Ashikari et al 1973). Axillary lymph nodes in ILC may remain palpable even when extensively involved (Grube et al 2002). A large study from the National Cancer Database to examine treatment and outcomes in patients with ILC showed a similar 5-year survival rate between patients with ILC and IDC, and between those ILC patients receiving breast-conserving therapy and those receiving mastectomy (Winchester et al 1998).

Paget's disease of the breast

Sir James Paget (1874) described 'an eczematous change in the skin of the nipple preceding an underlying mammary cancer', now known as Paget's disease (Paget 1874). More than 95% of women with Paget's disease of the nipple have an underlying malignancy, although 50% are clinically and mammographically undetectable (Vielh et al 1993). Paget's disease accounts for 0.7–4.9% of all breast malignancies, and misdiagnosis as eczema and treatment with topical steroids explains an average 10–12-month delay in diagnosis

(Kister and Haagensen 1970, Lagios et al 1984, Chaudary et al 1986, Dixon et al 1991, Kothari et al 2002). The first symptoms include burning, itching and change in sensation of the nipple–areola complex; raised skin lesions follow this, with a clear demarcation from the surrounding skin. Rarely, nipple deformity and retraction may occur if there is tethering from an underlying malignancy. Characteristically, it starts on the nipple and spreads to the areola and then surrounding skin, and in the later stages may present with ulceration and bleeding. Differential diagnoses include chronic eczema, benign papilloma of the nipple, basal cell carcinoma, Bowen's disease and malignant melanoma (Jamali et al 1996).

A full-thickness punch biopsy of the nipple should be performed to confirm the diagnosis (Rosen 1996). Mammography, ultrasonography and MRI can be used to detect an underlying mass, as well as assessing the contralateral breast. Paget's disease often presents with multicentric disease (75%); therefore, mastectomy is advocated as the procedure of choice (Kothari et al 2002). However, several small studies of BCS and radiotherapy for Paget's disease have shown low rates of recurrence (Fourquet et al 1987, Dixon et al 1991, Kollmorgen et al 1998, Bijker et al 2001, Fu et al 2001, Marshall et al 2003). Attempts to preserve uninvolved areas of the nipple are associated with high rates of local recurrence (Stockdale et al 1989, Fu et al 2001). Staging by SNB or axillary dissection is required for all patients with invasive disease.

Inflammatory breast cancer

Inflammatory breast cancer (IBC) was first coined by Lee and Tannenbaum at the Memorial Hospital, New York in 1924 to describe an aggressive form of breast cancer with an incidence of 1–6% (Lee and Tannenbaum 1924, Levine et al 1985). A higher incidence is reported in African-Americans than in Caucasians and other ethnic groups (10.1%, 6.2% and 5.1%, respectively). Women with IBC often present at a younger age than women with non-IBC (NIBC) (Chang et al 1998, Anderson et al 2003, Charafe-Jauffret et al 2004). The 10-year survival rate of patients with IBC is 26.7%, compared with 44.8% for those with NIBC (Low et al 2002). A recent review of 635 patients at the M.D. Anderson, Texas (IBC, $n = 214$; stage III NIBC, $n = 421$) demonstrated a significantly reduced progression-free survival for IBC compared with NIBC (24 months and 35 months, respectively), and of overall survival for IBC compared with NIBC (42 months and 60 months, respectively).

The criteria for diagnosis was described by Haagensen including erythema, oedema involving more than two-thirds of the breast, tenderness, induration, warmth, enlargement, peau d'orange and diffuseness of the tumour on palpation (Haagensen 1971). These symptoms progress rapidly. At diagnosis, most patients (55–85%) have axillary lymph node involvement and up to 30% have distant metastases (Jaiyesimi et al 1992, Hance et al 2005). Pathology shows extensive lymphovascular invasion by tumour emboli, involving the superficial dermal plexus of vessels in the papillary and high reticular dermis (Taylor and Meltzer 1938). Primary IBC is the development of carcinoma and skin changes in a previously healthy breast, and secondary IBC is the development of inflammatory IBC in a breast

Figure 47.2 Multifocal breast cancer. Most commonly seen in invasive lobular cancer. The left mammogram images [mediolateral oblique (MLO) and craniocaudal (CC)] have dense parenchyma and only show a single subtle mass with slight distortion (arrowhead) on the MLO view. Ultrasound shows two subtle lesions (arrowed) close to each other (LT BREAST 7.2 and 7.4). Contrast-enhanced subtraction magnetic resonance shows multiple enhancing lesions (arrow heads) in the left breast on different slices.

that has had a previous malignancy or changes caused by irradiation.

One treatment protocol from the M.D. Anderson advises initial treatment with neoadjuvant sequential taxane (paclitaxel/docetaxel) and an anthracycline-based regimen (5-fluorouracil + epirubicin + cyclophosphamide) (Cristofanilli et al 2002). Patients who show a partial or complete response undergo surgery (mastectomy and axillary dissection) followed by adjuvant radiotherapy and hormonal therapy (if ER α -positive). For those patients who do not respond, radiotherapy to the breast and axilla is recommended, followed by surgery, if feasible, and adjuvant hormonal therapy (if ER α -positive) (Singletary 2008). SNB is not recommended in patients with IBC as the identification rate is only 70% and the false-negative rate is 40% (Stearns et al 2002). Currently, most practitioners recommend a delayed reconstruction after completion of therapy. Most local recurrences occur in the mastectomy flap.

A number of studies have reported a higher incidence of c-erbB2 (HER-2) in patients with IBC (Turpin et al 2002, Parton et al 2004). One small study ($n = 22$, IBC = 9, NIBC = 13) combining docetaxel with trastuzumab as part of the primary systemic therapy observed a complete response in 40% of patients (van Pelt et al 2003). Lapatinib (reversible inhibitor of c-erbB1 and c-erbB2) has shown partial responses in women with IBC who have been extensively pretreated (Burriss et al 2005, Spector et al 2006). The combination of lapatinib with paclitaxel in a cohort of 21 chemotherapy-naïve IBC patients overexpressing HER-2 showed a clinical response rate of 95% (Cristofanilli et al 2006).

Other breast malignancies

Primary cutaneous melanoma of the skin of the breast is very rare, accounting for 0.28% of all cases of melanoma (Ariel and Caron 1972). It is more commonly found as a result of a distant metastasis from a primary elsewhere. A full history and physical examination for the presence of other melanomas should be performed. A core or surgical biopsy of the thickest portion of the melanoma will determine the depth of invasion. Immunostaining for HMB-45 and S100 enables differentiation of melanoma from other cutaneous masses. Staging is with computed tomography (CT) or positron emission tomography (PET), and lactate dehydrogenase levels should be measured. Wide local excision is recommended with margins dependent upon the depth of invasion, and SNB performed at the time of excision. Complete axillary dissection should be performed for those patients with clinically suspicious lymphadenopathy and those with melanomas larger than 4 mm (Essner et al 2002). Adjuvant therapy is similar to that for melanoma elsewhere in the body.

Radiation-induced primary angiosarcoma of the breast, first reported in 1981, is extremely rare (Maddox and Evans 1981). Approximately 60 cases have been reported, although the incidence is rising (Rao et al 2003). It presents as violet, blue, red or black skin nodules in a multifocal pattern, and is diagnosed by a punch, incisional or excisional biopsy (Fineberg and Rosen 1994). Fine needle aspiration, mammography and ultrasonography are often not helpful. Factor VIII-related antigen is positive in most angiosarcomas, dis-

tinguishing it from other sarcomas (Stokkel and Peterse 1992). Staging is based on the size, grade and depth of the tumour, with grade being the most important prognostic indicator. Most angiosarcomas are high grade and are treated with mastectomy (Fineberg and Rosen 1994). Axillary staging is not required, as most sarcomas do not metastasize to regional lymph nodes. The recurrence rate is 40% and prognosis is poor.

Primary breast lymphoma (PBL) is defined as a lymphoma localized to the breast and its draining basins, arising from lymphoid tissue in the breast (Smith et al 1987, Kuper-Hommel et al 2003). It accounts for 0.14% of all breast malignancies and 0.65% of all non-Hodgkin's lymphomas, with the most common type being diffuse large B-cell lymphoma (Ha et al 1998, Kuper-Hommel et al 2003). PBL arises most commonly in the seventh decade as a painless, enlarged rubbery mass. Mammographic and ultrasound findings are non-specific, and PBL is categorized according to the Ann Arbor classification of lymphomas. Diagnosis is by core biopsy, and the patient is staged by CT of the neck, chest, abdomen and pelvis, and bone marrow biopsy. Surgery with adjuvant radiotherapy is no longer advocated due to the high incidence of local and disseminated recurrence (Kuper-Hommel et al 2003). Treatment of PBL is now with chemotherapy, followed by targeted radiotherapy, with a 2-year survival rate of 63% (Ha et al 1998, Brogi and Harris 1999).

Metastasis to the breast

This is uncommon and accounts for 0.5–6.6% of breast malignancies, with the contralateral breast being the most common site of metastatic malignancy (Bohman et al 1982, Paulus and Libshitz 1982, Amichetti et al 1990). Other malignancies that metastasize to the breast include lymphoma, melanoma, rhabdomyosarcoma and small cell lung cancer (Bartella et al 2003). These lesions are indistinguishable from primary breast cancers by examination and imaging. Core biopsy is preferable as immunohistochemistry plays an important role in diagnosis and prognosis is poor, with a 1-year survival rate of 20% (Bartella et al 2003).

Presentation

Breast cancers may present symptomatically or through screening.

Breast screening

Breast screening aims to reduce mortality through early detection. A number of trials carried out between the 1960s and 1980s showed that population screening by mammography can be expected to reduce breast cancer mortality by 25% (Olsen and Gotzsche 2001, Tabar et al 2001, Anonymous 2002b, Duffy et al 2002, Nystrom et al 2002). The benefit of screening is greatest in women aged 55–70 years (Anonymous 2002b, Nystrom et al 2002). There is no mortality benefit of screening women under 40 years of age, and the mortality benefit of those aged between 40 and 55 years is 20% (Anonymous 2002b, Nystrom et al 2002). Breast screening has been introduced in many countries over

the past 20 years. In some countries, screening is advised in all women over 40 years of age; however, in countries providing population-based screening, women over 50 years of age are targeted.

The UK National Breast Screening Programme (NHSBSP) was set up by the Department of Health in 1988 in response to the recommendations of a working group, chaired by Professor Sir Patrick Forrest, which had been set up to consider whether or not to implement a population screening programme in the UK. The report 'Breast Cancer Screening' was published in 1986, and became known as 'The Forrest Report' (Forrest 1986). The NHSBSP was the first of its kind in the world. It began inviting women for screening in 1988, and national coverage was achieved by the mid 1990s. It provides screening by invitation, free at the point of delivery to all women between 50 and 70 years of age (initially 50–64 years, age range increased in 2004). Women over 70 years of age can attend but are not invited, and more than 70% of the invited population are required to attend in order to obtain an overall mortality benefit. The screening method is two-view mammography (cranio-caudal and medio-lateral oblique views) every 3 years. Approximately 5% of women screened are recalled for further assessment of a problem identified at screening. Three-quarters of women recalled simply require further imaging (ultrasound and/or mammography) and clinical assessment before being reassured and discharged. The remaining 25% will undergo a needle biopsy procedure in order to diagnose six cancers per 1000 women screened. Despite advances in needle biopsy techniques, 0.25% of all women screened will require an open surgical biopsy. Mammography can be expected to detect breast cancer 2 years before it becomes clinically apparent, and the frequency of mammography is determined by the lead time of breast cancer. Mammographic screening intervals, based on average growth time of breast cancer to age, should be yearly for women between 40 and 50 years of age, every 2 years in women between 50 and 60 years of age, and every 3 years thereafter. However, the Breast Screening Frequency trial did not show a significant benefit for women aged 50–64 years screened yearly compared with those screened every 3 years (Anonymous 2002a). One-third of breast cancers will present in the interval between screens, called 'interval cancers', and half of these will present in the third year after screening.

Screening high-risk young women

A national study evaluating mammographic screening for young women with a family history of breast cancer is being conducted (FH01 study), comparing screening in women aged 40–44 years with a moderate risk with a control arm; this study is currently unreported. Mammography has a higher predictive value in young women at high risk compared with age-matched controls, but is not sensitive, particularly in women with *BRCA1* mutations (Chang et al 1999, Brekelmans et al 2001, Goffin et al 2001, Tilanus-Linthorst et al 2002, Hamilton et al 2004, Robson 2004, Warner et al 2004). Women with *BRCA1* rarely present with associated DCIS, and the mammographic features are therefore usually of a mass lesion with no microcalcifications and no architectural distortion.

These often present as interval cancers. *BRCA2* cancers present similarly to sporadic cancers, and are more likely to be detected by mammography. Ultrasonographic features in *BRCA1* cancers are often indeterminate or benign.

MRI is the most sensitive imaging modality in young women (Kriege et al 2004, Robson 2004). Genetically predisposed women commonly develop breast cancer when young and when dense breast tissue reduces the sensitivity of mammography. The Magnetic Resonance Imaging for Breast Screening (MARIBS) study compared the performance of contrast-enhanced MRI with mammography in this group of women (Leach et al 2005). It confirmed that contrast-enhanced MRI was significantly more sensitive than mammography in cancer detection for the entire cohort, but especially in the subgroup of *BRCA1* carriers. Specificity for both procedures was acceptable. In spite of a high proportion of grade 3 tumours, the tumours were small and few women were node positive. These findings confirm those from the Netherlands six-centre MRI Screening (MRISC) study and a single-centre study from Toronto (Warner et al 2004, Kriege et al 2007). These reports support a policy of annual screening combining contrast-enhanced MRI and mammography, which would detect most tumours. These studies show evidence of effective small cancer detection, but do not have sufficient power to show whether mortality is reduced, for which there is no current evidence. Age for starting screening must be based on age rather than age of affected relatives. For women at moderate risk, screening should be started at 40 years of age, and for those at high risk, screening may be started at 30–35 years of age. High risk can be described as more than 8% by 50 years or more than 25% for lifetime. It is important that these women be followed-up in a specialist centre.

Symptomatic disease

Approximately 60% of breast cancers present symptomatically with a discrete mass, skin changes (ulceration/dimpling), nipple changes or, rarely, pain (mastalgia). In the UK, guidelines have been issued by the Department of Health informing family practitioners of the suspicious symptoms which warrant urgent referral to a breast clinic. Referral must be within 24 h of seeing their general practitioner, and women should be seen by a specialist in a breast clinic within 2 weeks of referral. 'One-stop' clinics, where all the necessary tests required to make a diagnosis are performed, are recommended.

Diagnosis

The management of women with breast cancer should be undertaken in a specialist breast multidisciplinary unit, with members of the breast team divided into two separate but interdependent groups:

- Diagnostic team, including breast specialist clinician (normally a consultant breast surgeon), specialist radiographer and radiologist, pathologist (histopathologist/cytopathologist), breast care nurses, nurse practitioners, clinical staff, administrative staff and a dedicated multidisciplinary team (MDT) coordinator.

- Cancer treatment team, including members of the diagnostic team and clinical/medical oncologist, oncoplastic/plastic surgeon, medical geneticist, research/ward/breast care nurses, lymphoedema specialist, clinical psychologist, palliative care team and data management personnel.

Triple assessment

Patients undergo a triple assessment, which is a combination of clinical examination, imaging (mammography for women >35 years and ultrasonography for women <35 years) and cytology (fine needle aspiration) with or without needle core biopsy (both guided by either X-ray or ultrasonography). Triple assessment has a high positive predictive value and a low false-positive rate. The aim of triple assessment is to make a diagnosis prior to counselling and definitive treatment.

Mammography

X-ray mammography has been the basis of breast imaging for more than 30 years. The sensitivity of mammography for breast cancer is dependent on age, as the denser the breast tissue, the less effective it is in detection (Figure 47.3). Breast tissue is more dense in younger women and whilst the sensitivity of mammography for breast cancer in women over 60 years of age approaches 95%, detection rates are less than 50% in women under 40 years of age (Kolb et al 2002). Mammography uses ionizing radiation and should only be used where a clinical benefit is likely. The benefits of mammography in women over 40 years of age is likely to outweigh the oncogenic effects of repeated exposure. There is rarely an indication for performing mammography in women under 35 years of age unless there is a strong clinical suspicion of malignancy. The false-negative rate for mammography has been reported to be between 10% and 30%. Although many cancers are mammographically occult, espe-

Figure 47.3 Invasive ductal carcinoma grade II mammogram. Irregular dense mass with a spiculated margin and fine spiculations extending out into the surrounding breast tissue. The spiculations are causing distortion and skin thickening (open arrows).

cially in dense breasts, a large number of these are visible retrospectively. These oversights can be reduced by double reading, improving sensitivity by up to 15% (Skaane et al 2007). Computer-aided design (CAD) programmes are available to assist radiologists to detect potentially suspicious abnormalities.

Ultrasound

High-frequency ultrasound (>10 MHz) is a highly effective diagnostic tool in the investigation of focal breast symptoms (Wilson and Teh 1998). Ultrasound does not use ionizing radiation and has a very high sensitivity for breast pathology (Lister et al 1998). High-resolution ultrasonography can easily distinguish between most solid and cystic lesions, and can differentiate between benign and malignant lesions with a high degree of accuracy (Figure 47.4). It is the technique of choice for further investigation of focal symptomatic breast abnormalities for women under 35 years of age, and is used in conjunction with mammography in those over 35 years of age. Ultrasound is being used increasingly to assess the axilla in women with breast cancer. Those nodes with an abnormal morphology can be accurately sampled by fine needle aspiration.

Elastography ultrasound is a new adjunct to conventional B-mode ultrasound imaging, and uses the differences in tissue deformation to create an image of relative tissue stiffness (Wakeham et al 2006). Objects in the breast of different stiffness will displace different amounts, creating an image of relative stiffness (Svensson and Amiras 2006). Research into elasticity ultrasound has been ongoing for over 20 years, but it is only more recently with advances in computing power that commercial development of the potential clinical applications has become possible. A recent study has shown that benign lesions have a smaller size image on strain ultrasound than B-mode imaging, whilst malignant lesions usually have a larger strain image (Hall et al 2003). Malignant lesions mainly appear as stiff throughout, and strain imaging can reveal lesions that are occult on B-mode imaging, allowing accurate diagnostic biopsy. It may be that knowledge of the typical strain appearances may obviate the need to fine needle aspirate/biopsy certain benign lesions.

Magnetic resonance imaging

MRI of the breast is an important new investigation to evaluate breast cancer. Studies have shown almost 100% sensitivity in detecting invasive breast cancers, although most show poor specificity. Diagnostic breast MRI should be performed with a high field strength (>1.5 tesla) magnet with a dedicated breast radiofrequency coil. Contrast enhancement with gadopentate dimeglumine (Gd-DTPA) is essential in identifying breast cancers and distinguishing malignancies from benign masses. The role of MRI is evolving, and one of its most widely used indications is in preoperative evaluation of known tumours for size, extent of disease, multicentricity and multifocality (especially invasive lobular carcinoma). Few centres offer magnetic-resonance-guided breast biopsy, but most breast lesions over 10 mm seen on MRI can be visualized by ultrasound.

A Memorial Sloan-Kettering Cancer Center study of patients with invasive lobular cancer showed that MRI iden-

Figure 47.4 Invasive ductal carcinoma grade II ultrasound. This is the same tumour as shown in Figure 47.3. On the greyscale image, there is an irregular mass of reduced echogenicity which has posterior shadowing. The colour Doppler image shows surround vascularity which has a radial distribution feeding the cancer. Slight overlying skin thickening can be seen on the greyscale image.

Figure 47.5 Magnetic resonance of ruptured prosthesis. Note the prosthesis lies behind the pectoral muscle (arrow heads). The right prosthesis has ruptured, and the curvilinear shape of the envelope of the prosthesis lying free within the silicone is clearly visible.

tified 27% more sites of cancer in the ipsilateral breast. Of these, 42% had DCIS and 58% had an infiltrating cancer (Quan et al 2003). Of the 62 women studied, multifocal cancer was present in 20%, multicentric cancer in 4%, and multifocal and multicentric cancer in 3%. Therefore, approximately one-quarter of additional ipsilateral cancers occur within the same quadrant. A recent multi-institutional study of women recently diagnosed with breast cancer showed that 3.1% had a cancer detected by MRI in an apparently uninvolved contralateral breast (Lehman et al 2007). MRI has been shown to accurately distinguish between scarring and tumour recurrence, provided that the scan is performed more than 18 months after surgery. The value of MRI screening in high-risk patients has been discussed previously. MRI is used to evaluate the integrity of saline and silicone implants (Figure 47.5), to discern extracapsular rupture from intracapsular rupture, and to identify silicone within the breast parenchyma (Holmich et al 2005). It is superior to

Figure 47.6 Leaking silicone breast prosthesis. Extended field of view image of a leaking prosthesis. The blue arrow shows free silicone outside the envelope of the prosthesis. There is increased echogenicity with a comet's tail of reverberation echogenicity deep to it. In the axilla, free silicone is demonstrated by the white arrow; again, there is increased echogenicity with a comet's tail of reverberation deep to it.

ultrasonography (Figure 47.6) in detecting implant ruptures in patients with both double and single lumen implants (Di Benedetto et al 2008).

Positron emission tomography

Most breast malignancies have greater metabolism and concentrate ^{18}F -fluorodeoxyglucose (FDG), the agent most frequently used in clinical PET. PET and PET/CT the latter of which combines anatomical and physiological imaging are increasingly used in oncology (Figure 47.7). However, it is

Figure 47.7 Positron emission tomography (PET)/computed tomography (CT) of breast carcinoma liver metastases. The whole-body PET image shows the extent of metastatic disease because of increased metabolic activity in the metastases demonstrated by the uptake of fluorodeoxyglucose, labelled with fluorine-18 (a positron emitter). The fused PET/CT images show the exact anatomical location of the metastases in mediastinal nodes, liver and left ilium adjacent to the anterior part of the sacroiliac joint. The colour denotes the increased metabolic activity which can be measured. The standard uptake value allows changes in metabolism to be detected, enabling assessment of whether or not metastases are responding to chemotherapy regimes before anatomical change occurs.

widely agreed that FDG-PET does not have a role in the detection of primary breast cancer.

FDG-PET and FDG-PET/CT can improve staging by detecting otherwise occult disease, particularly in the locoregional and mediastinal nodal basins (Eubank et al 2004, Eubank and Mankoff 2005). Eubank et al showed that FDG-PET detected more widespread disease changes, affecting treatment in up to 44% of patients thought to have locoregional recurrence. Skeletal metastases account for 90% of all metastatic lesions, as well as being the most common site of initial metastatic involvement. A number of studies have shown that FDG-PET is superior to bone scintigraphy in

detecting intramedullary and lytic lesions, but often fails to demonstrate blastic lesions, which are readily detected by bone scintigraphy (Cook et al 1998, Moon et al 1998, Kim et al 2001, Even-Sapir et al 2004, Isasi et al 2005, Nakai et al 2005, Tatsumi et al 2006).

Recently, a study of FDG-PET/CT evaluating asymptomatic breast cancer patients with rising tumour markers demonstrated 90% sensitivity for diagnosing recurrent tumour, affecting the clinical management in 51% of patients (Radan et al 2006). A number of studies have demonstrated the accuracy of FDG-PET in depicting response to treatment (Wahl et al 1993, Schelling et al 2000, Smith et al 2000,

Chen et al 2004, Mankoff and Eubank 2006, Rousseau et al 2006). More recently, a decline in FDG uptake of more than 50% indicated a good response to treatment in the metastatic setting (Gennari et al 2000). One study demonstrated a change in FDG uptake after one cycle of chemotherapy, and an absence of FDG uptake following completion of treatment predicted a better survival than in those patients with residual FDG-positive disease (Cachin et al 2006).

Image-Guided Biopsy

Fine needle aspiration cytology

Fine needle aspiration cytology (FNAC) of breast lumps is an important part of the triple assessment of the palpable breast lump. FNAC of breast masses has been shown to be a simple and safe diagnostic procedure. However, diagnostic failure of aspiration cytology has been attributed to a high unsatisfactory aspirate rate. This may be due to either insufficient epithelial cells present, equivocal smears or unrepresentative aspirates resulting in false-negative diagnoses. However, some patients find FNAC painful; it can be associated with haematoma formation; and, if performed before mammography or ultrasound, it can make radiological assessment of the breast more difficult.

Needle core biopsy

Automated core biopsy (14 G, 22 mm) provides significantly better sensitivity, specificity and positive predictive value than FNAC (Teh et al 1998, Britton 1999, Britton and McCann 1999, Vargas et al 2000). Most units in the NHSBSP now perform automated core biopsy as the primary diagnostic tool. Ultrasound provides real-time visualization of the biopsy procedure, and confirmation of sampling. Between 80% and 90% of breast abnormalities can be visualized on ultrasound, with the rest being performed under stereotactic X-ray guidance. Needle core biopsy is highly accurate in determining the nature of most breast lesions, and women with benign lesions can avoid unnecessary surgery. For those with breast cancer, needle biopsy provides an accurate diagnosis enabling physicians to make informed management decisions. Needle biopsy provides histology and tumour grade. A non-operative diagnosis should be possible in more than 90% of invasive cancers and 85% of non-invasive cancers.

Some lesions only visible on MRI may require MRI guidance for biopsy. The likelihood that a clinically palpable lesion which cannot be visualized on mammography and ultrasonography is malignant is less than 1%. In these circumstances, it is important to carry out a freehand biopsy to exclude the possibility of a diffuse malignant mass such as lobular carcinoma. The number of core specimens obtained should reflect the nature of the abnormality being sampled. For a suspicion of a carcinoma, it is recommended that at least two core specimens should be taken. For a stereotactic biopsy, a minimum of five core biopsies should be taken. In the event of a sampling error, either a repeat biopsy or an open excision biopsy can be performed.

Vacuum-assisted mammotome

When there is diagnostic uncertainty, 8 G vacuum-assisted mammotome can be used to obtain larger tissue volumes (approximately 300 mg/core) (Heywang-Kobrunner et al 1998, Brem et al 2001, Parker et al 2001). This is very successful for improving the diagnostic accuracy of borderline breast lesions and at sites where it is difficult to biopsy using other techniques. Indications for use include: small mass lesions, architectural distortions, failed needle biopsy, small clusters of microcalcifications, excision of small benign lesions and diffuse non-specific lesions. Two other types of vacuum-assisted core biopsy systems include minimally invasive breast biopsy and automated tissue excision and collection (an MRI-guided vacuum-assisted breast biopsy system).

Advanced breast biopsy instrumentation

Advanced breast biopsy instrumentation (ABBI) is used for surgical stereotactic biopsy of non-palpable breast lesions under radiographic guidance. This biopsy was developed for both diagnosis and therapy. ABBI requires an incision of 5–20 mm, is restricted to use on a prone table and requires the insertion of a localizing T-wire. This vacuum-assisted biopsy obtains a large cylinder of tissue from the subcutaneous tissue down to and beyond the lesion with an electrocautery snare. ABBI removes a larger volume of tissue, theoretically increasing the diagnostic accuracy of the biopsy. Failure rates of up to 31.5% have been reported due to poor patient selection, technical problems with the T bar and failure to remove tissue. Complication rates of ABBI procedures requiring intervention are significantly higher than those of core biopsy (1.1% and 0.2%, respectively). Complete removal of small lesions does occur and positive margins of 19–100% have been reported (Leibman et al 1999, Matthews and Williams 1999). ABBI is more expensive than any other percutaneous needle biopsy technique.

Open surgical biopsy

Diagnostic excision biopsy is now uncommon but is still required for definitive histology of some breast lesions graded B3/4 or C3/4. To minimize patient anxiety, an operation for diagnostic purposes should be performed within 2 weeks of the decision to operate. For patients having surgical removal of a proven benign lesion in the National Health Service (UK), an 18-week waiting time applies. Any benign diagnostic resection specimen weighing more than 40 g should be discussed at the postoperative MDT meeting and any mitigating reasons should be recorded.

Staging Investigations

Staging investigations in the absence of specific symptoms are not performed when patients have been diagnosed with breast cancer. Breast cancer is staged by the Tumour, Node, Metastasis system based on the International Union against Cancer criteria. This enables comparison of results of trials worldwide and provides information that can be used to inform treatment regimens. There is a degree of

bias depending on the extent of axillary surgery, completeness of excision and staging investigations performed.

Treatment Planning and Patient Communication

The management of breast cancer within the context of an MDT of specialists facilitates rapid and accurate diagnosis as well as selection of appropriate treatment for all stages of disease. The specialist breast care team includes research nurses and specialist nurses that have a vital role in support and counselling patients. Breaking bad news requires time, patience, sensitivity and compassion. It is important to create an environment in which a patient can secure the information, autonomy and support that suits their need. Patients must be given adequate time, information and support in order to make a fully informed decision concerning their treatment.

A preoperative search for occult metastases by bone scan and liver ultrasound does not yield useful information in patients with operable primary breast cancer (Bishop et al 1979). Preoperative chest X-ray and relevant blood tests (full blood count, liver function tests and routine biochemistry) are agreed by local protocol.

Surgery and Radiotherapy

Surgery

The breast

The aim of breast cancer surgery is to achieve long-term local disease control with the minimum of morbidity. The majority of women diagnosed with breast cancer will have small breast cancers, suitable for BCS. The aims of BCS are to produce an acceptable cosmetic appearance and lower psychological morbidity (improved body image, sexuality and esteem) compared with mastectomy. Two studies have shown equivalence in terms of outcome for BCS compared with mastectomy (Anonymous 1995, Morris et al 1997). Meta-analysis of five trials comparing BCS with mastectomy involving 3006 women found no significant difference in the risk of death at 10 years (Anonymous 1995). It is important to ensure that only appropriate patients are selected for BCS, with the aim of minimizing local recurrence whilst achieving a good cosmetic outcome. Single cancers less than 4 cm in size can usually be managed by BCS. Many units have a 3-cm cut-off and lying more than 2 cm from the nipple–areolar complex for considering BCS, but it is the balance between tumour size and breast volume which determines whether or not a patient is suitable for BCS. For patients with large tumours, neoadjuvant chemotherapy can be considered.

Patients with multiple tumours in the same breast should not be considered for BCS as they have a high incidence of recurrence so are best treated with mastectomy with or without reconstruction (Fisher et al 1986, Kurtz et al 1990). Patients with two tumours in close proximity can be candidates for BCS provided that all disease is excised with clear margins. The aim of wide local excision is to remove all invasive and in-situ carcinoma with a 1-cm

macroscopic margin of normal surrounding tissue. Incomplete excision rates should be approximately 10–25% and the most common problem following surgery is poor cosmetic result.

Women having more than 10–20% of breast volume removed are likely to have a poor cosmetic result (Cochrane et al 2003). Factors influencing local recurrence include young age (<40 years), tumour grade, presence of an extensive in-situ component and lymphovascular invasion (Holland et al 1990a, Anonymous 1991). More than 80% of local recurrences will occur at the site of previous cancer. Local recurrence following BCS is usually best treated with mastectomy, although re-excision is possible should the recurrence occur more than 5 years after initial treatment, as these are classified as a second primary cancer rather than recurrent disease. Local recurrence after 5 years is associated with a much better prognosis than recurrence within 5 years. The recently reported UK Standardisation of Breast Radiotherapy Trial (START) has demonstrated low rates of recurrence (3.5% at 5 years) following BCS (Dewar et al 2007). Local recurrence rates for invasive cancer after BCS should be less than 5% at 5 years with a target of less than 3% at 5 years.

The axilla

Management of the axilla is a subject of great debate. Surgical treatment of the axilla is two-fold, firstly in disease control and secondly in staging. Surgical staging of the axilla is by axillary lymph node dissection (ALND) for the majority of women, with data regarding nodal status being the most powerful variable in the prognosis for primary breast cancer. Disease-free interval and overall survival are directly related to the number of axillary nodes that contain metastases (Fisher et al 1984, Carter et al 1989). ALND provides the most accurate qualitative and quantitative assessment of the axilla, with the probability of lymph node involvement related to the size of the primary tumour. In small tumours with a size of approximately 10 mm, the risk of nodal metastases is 10% (Baxter et al 1996, Kollias et al 1999). Recurrence rates of 3–5% at 5 years have been reported following ALND, and it has been suggested that the axillary node recurrence rate should be less than 5% with a target of less than 3% (Fowble et al 1989, Siegel et al 1990, Halverson et al 1993, Forrest et al 1995).

Routine histological examination of dissected axillary lymph nodes may be inadequate in identifying the presence of small metastatic tumour deposits or 'micrometastases'. This has been described as a small cluster of cells measuring 0.2–2 mm. Studies have shown that it is possible to identify micrometastases in 50% of 'negative' lymph node cases using serial axillary sections, immunohistochemistry and polymerase chain reaction to detect mRNA transcripts (Trojani et al 1987, Hainsworth et al 1993, Mann et al 2000). Recent studies have shown that cases initially deemed to be 'node negative' but subsequently shown to have micrometastases are associated with a worse outcome (Huvsos et al 1971, Fisher et al 1978, Rosen et al 1981, Friedman et al 1988, Anonymous 1990, Clayton and Hopkins 1993, McGuckin et al 1996, Dowlatshahi et al 1997).

Significant morbidity is associated with axillary dissection, including seroma, wound infection, reduced shoulder

mobility, motor nerve damage (median pectoral nerve, long thoracic nerve of Bell, thoracodorsal nerve), numbness and paraesthesia (80%), and lymphoedema (Siegel et al 1990, Shaw and Rumball 1990, Hladiuk et al 1992, Lin et al 1993). Lymphoedema incidence has been reported to be between 10% and 25%, with hypertension and BMI being risk factors. A 40% incidence of lymphoedema has been reported in those patients undergoing ALND and radiotherapy to the axilla.

Cabanas first proposed the concept of SNB for penile cancer in 1977, followed by Morton for melanoma in 1992 (Cabanas 1977, Cochran et al 1992, Morton 1997). Krag et al first published the use of SNB in breast cancer in 1993 (Krag et al 1993). SNB is based on the knowledge that for any given tumour-bearing site, there is orderly progression of lymph drainage to a draining lymph node (sentinel node). It relies on the premise that skip metastases do not occur, and that the absence of tumour of the sentinel lymph node implies that the entire lymphatic bed is clear of metastatic disease. The aim of SNB is to provide accurate axillary staging by use of a minimally invasive surgical procedure and significantly reduced morbidity. The sentinel lymph

nodes are identified using a radioisotope (Figures 47.8 and 47.9), injected on the day of surgery, and a coloured patent blue dye injected peritumorally or interdermally in the peri- and subareolar region 5–10 min before surgery with the breast gently massaged; this leads to an identification rate of 97% (Albertini et al 1996, Veronesi et al 1997, Cody 1999). Intraoperative identification of the sentinel lymph node is confirmed by a hand-held gamma probe, and visually by blue staining of the node. Risk factors of the procedure include allergic and anaphylactic reactions to the blue dye (Mullan et al 2001). Exposure to clinical staff from the radioisotope is negligible.

One disadvantage of SNB is that women with a positive sentinel node will require a second operation to clear the axilla. Intraoperative frozen section and imprint cytology have been used to assess the status of the sentinel nodes; however, neither procedure has proved acceptable. A small trial evaluating intraoperative reverse-transcriptase polymerase chain reaction (assay time 20–30 min) for epithelial markers mammaglobin and cytokeratin 19 has shown sensitivity of 96%, specificity of 100% and a positive predictive value of 100% for sentinel node detection (Cutress et al

Figure 47.8 Axillary sentinel lymph node dynamic study. Images taken at 1-min intervals showing initial drainage through the draining lymphatic and filling of the (A) sentinel node with uptake into the second-order nodes (B) on subsequent images.

Figure 47.9 Axillary sentinel lymph node. Anterior view of breast sentinel lymph node imaging. A, periareolar injection site where technetium-99m radiolabelled macroaggregated albumin has been injected; B, draining lymphatic; C, sentinel lymph node at level 1; D, two second-order lymph nodes which have filled after the sentinel lymph node and lie at level 2. There is a radioactive flood source behind the patient to outline the anatomy. The white arrows point to the left mediastinal and cardiac border.

2008). In most studies, the number of sentinel lymph nodes identified ranged from 1.5 to 4.0, and recent studies have shown that, in a small number of cases, the sentinel lymph node was beyond the first two lymph nodes removed (McCarter et al 2001, Zervos et al 2001, Kennedy et al 2003). McCarter et al claimed that at least three nodes are required to identify 99% of node-positive patients, and the false-negative rate is significantly higher (16.5%) when only one lymph node is removed (McCarter et al 2001). Goyal has shown that 99.6% of metastases from node-positive tumours are found within the first four nodes, suggesting that between two and four nodes should be removed for optimum staging of the axilla (Goyal et al 2005).

Multifocality and multicentricity, once thought to be a relative contraindication to SNB, now appears to be feasible and accurate with an acceptably low false-negative rate, and can be used in patients presenting with a clinically negative axilla (Kumar et al 2003, Goyal et al 2004). Currently, there are no randomized controlled trials addressing the feasibility, accuracy or timing of SNB in neoadjuvant chemotherapy. A meta-analysis assessing the reliability of SNB in patients following neoadjuvant chemotherapy reported sensitivity of 88% (Xing et al 2006). Some centres advocate SNB at diagnosis, prior to initiation of neoadjuvant chemotherapy.

The increase in BCS for early breast cancer has resulted in a 10-year risk of ipsilateral recurrent breast cancer of 10–20% (Fisher et al 1989a, van Dongen et al 2000). This has resulted in an increasing population with ipsilateral tumour recurrence with prior axillary surgery, who were traditionally treated with salvage mastectomy and axillary node dissection. However, emerging data indicate that there may be a role for SNB in identifying aberrant lymphatic drainage patterns in recurrent breast cancer (Intra et al 2005, Roumen

et al 2006, Taback et al 2006). The incidence of axillary disease in patients with DCIS (6–9%) is greater in a subset of patients with microinvasion, younger patients, DCIS (>4 cm) and those with high-grade disease (Silverstein et al 1991, Cox et al 2000, Pendas et al 2000, Leonard and Swain 2004, Yen et al 2005). Current guidelines from the American Society of Clinical Oncology (ASCO) only recommend SNB in those patients undergoing mastectomy for DCIS, as an incidental invasive component is seen in 20% of these patients (Meyer et al 1999, Lyman et al 2005).

Internal mammary nodes (IMN) have been shown to have prognostic significance (Lacour et al 1983). IMN have been successfully biopsied in 60–85% of cases, with a prevalence of metastases in 5–27% of cases, resulting in upstaging and/or a change in management in 2–8% of patients. Whilst not standard practice, sentinel biopsy of IMN requires further investigation to determine efficacy and safety.

SNB is a new procedure, so long-term follow-up for axillary recurrence will be the ultimate measurement of its success. To date, the rate of axillary recurrence is lower than anticipated given the average false-negative rate of 5–6%. Non-operative staging of the axilla remains elusive. Clinical examination is unreliable, with sensitivity varying from 30% to 75% and specificity approaching 50%. Ultrasound in combination with FNAC can identify 40–45% of patients with involved nodes. PET has shown some promising early results, with sensitivity of 75% and specificity of 90%. Some Italian centres are using PET to assess the need for SNB in low-risk, clinically node-negative patients with a low probability of nodal involvement (Greco et al 2001).

Radiotherapy/radiation therapy

Breast radiotherapy

Multiple randomized trials have shown that radiotherapy substantially reduces the risk of local recurrence following BCS. Adjuvant radiotherapy aims to reduce the risk of locoregional recurrence and improve overall survival. Radiotherapy is not routinely given after mastectomy but tends to be reserved for those with large (>4 cm), high-grade tumours, direct invasion of the skin or pectoral fascia, and extensive nodal involvement who are at high risk of local recurrence. The 1995 Early Breast Cancer Trialists' Collaborative Group confirmed that locoregional recurrence was reduced by 66% with postmastectomy radiotherapy (Anonymous 1995). This trial confirmed a reduced risk of breast cancer with radiotherapy, but an increased risk of death from other causes (cardiac deaths). Recent randomized trials of women treated with more modern radiotherapy have confirmed that postmastectomy radiotherapy will prevent one death for every 11 women treated, and one locoregional recurrence for every three to five women treated (Ragaz et al 1997, Overgaard et al 1999).

It is important to define the group of patients in whom radiotherapy is required and the group in whom it is not. One recent trial showed no increase in survival on addition of radiotherapy to women over 70 years of age being treated with tamoxifen who were ER α positive with no nodal involvement and tumours less than 2 cm in size (Hughes et al 2004, Bentzen et al 2008).

Hypofractionation radiotherapy aims to deliver an increased dose of radiotherapy over a reduced time frame. The START trial has demonstrated equivalent recurrence rates at 5 years for patients with early-stage breast cancer. The Faster Radiotherapy for Breast Cancer Patients (FAST) trial is currently comparing larger doses (5.7–6 Gy) of radiotherapy given once weekly for 5 weeks with the standard daily 2-Gy treatment (Yarnold et al 2004).

The Targeted Intraoperative Radiotherapy Trial (TARGIT) is evaluating single-dose intraoperative radiotherapy using a low-energy X-ray source (50 kV) as an alternative to conventional postoperative radiotherapy for treatment of early-stage invasive breast cancer. The single-day targeted intraoperative radiotherapy is designed to administer the highest dose of radiotherapy to a distance of 1 cm surrounding the lumpectomy cavity, while sparing the nearby normal breast, chest and shoulder from the effects of radiation.

Axillary radiotherapy

Irradiation of lymph glands is advised if there is nodal involvement on sampling, SNB and level 1 dissection, and no further surgery is planned. Supraclavicular fossa irradiation is indicated in patients with more than four involved axillary lymph nodes and if the axillary has been cleared. Irradiation of a fully dissected axilla should be avoided unless there is extensive extracapsular tumour extension. The risk of lymphoedema following a full axillary dissection is increased to 40%.

Peri- and Postoperative Care

Patients should be supported by a breast care nurse who must have good links with outpatient, ward and community nurses to assist in continuity of care. Breast care nurses should assist in the fitting of breast prostheses following mastectomy, inform patients about the range of services available and provide them with literature including details of local self-help groups. The breast care team should ensure that primary care practitioners have a clear understanding of the diagnosis, care plan and toxicity profile of any proposed treatment. Following surgery, all patients with breast cancer should have their results discussed at an MDT meeting, where postoperative histology can be discussed and the need for further surgical treatment and/or adjuvant treatment discussed and recorded.

Endocrine Therapy

Breast cancer was the first malignancy for which systemic therapy was developed. The link between hormones and breast cancer growth and development has been recognized for more than a century. In 1896, George Beatson reported that removal of the ovaries from premenopausal women with advanced breast cancer produced a dramatic decrease in tumour size and improved the patient's prognosis (Beatson 1896). In 1900, Stanley Boyd at Charing Cross Hospital accumulated the national case reports of oophorectomy, and noted that only one-third of patients responded to ovarian

ablation and responses lasted, on average, for 1–2 years (Boyd 1900).

Discovery that oestrogenic hormones were produced in the ovary prompted the search for therapeutic antagonists to reduce the incidence of breast cancer in individuals predisposed to the disease by their sensitivity to oestrogenic hormones (Allen and Doisy 1923). Subsequent laboratory, epidemiological and clinical studies have established that oestrogens stimulate the growth of breast cancers (Lacassagne 1936). Oestrogen actions are mediated by two oestrogen receptors, ER α and ER β , which are members of the nuclear receptor superfamily of transcription factors that regulate the expression of responsive genes upon binding to their cognate ligand (Chawla et al 2001). Whilst the importance of ER β in breast cancer is at present unresolved, ER α is expressed in the majority of breast cancers and its presence correlates with response to endocrine therapies (Fuqua et al 2003). Thus, current clinical practice involves determination of the ER α status of the malignant cells, followed by adjuvant treatment of ER α -positive cases with endocrine agents that inhibit ER α activity.

Inhibition of ER α activity is achieved with two main strategies: using antioestrogens, primarily tamoxifen, that bind to ER α to inhibit its activity; or by blocking oestrogen synthesis, such that ER α is not activated. Peripheral oestrogen synthesis is the main source of oestrogens in postmenopausal women, and drugs that reduce peripheral oestrogen synthesis, by blocking the activity of the aromatase enzyme, are being used as second- and third-line agents in hormone-sensitive disease once resistance to tamoxifen has developed (Johnston and Dowsett 2003).

Tamoxifen

Tamoxifen, a non-steroidal antioestrogen, is currently the most common form of endocrine therapy for women with ER α -positive breast cancer. Tamoxifen is a selective estrogen receptor modulator (SERM) which has partial agonist activity in some tissues, including bone, lipids and endometrium, but antagonist activity in breast tissue. The antitumour effect of tamoxifen is mediated via competitive inhibition of oestrogen binding to ERs. In women with ER α -positive breast cancer, 5 years of tamoxifen results in a 41% relative risk reduction of recurrence and a 34% relative risk reduction of death (Anonymous 2005). The National Surgical Adjuvant Breast and Bowel Project (NSABP) B-14 trial and the Scottish Adjuvant Tamoxifen trial demonstrated no benefit in taking tamoxifen for more than 5 years; in contrast, the Eastern Cooperative Oncology Group (ECOG) trial studying indefinite tamoxifen therapy in node-positive patients showed a statistically significant improvement in disease-free survival with extended tamoxifen (Tormey et al 1996, Fisher et al 2001, Stewart et al 2001). The adjuvant Tamoxifen Treatment — Offer More? (ATTOM) and Adjuvant Tamoxifen — Longer against Shorter (ATLAS) trials examining the efficacy of long-term tamoxifen had consistent findings, reporting increased disease-free survival but no overall survival advantage for long-term tamoxifen.

Tamoxifen is generally well tolerated, with the most common side-effects being hot flushes (50% of women), vaginal discharge and irregular menses (Fisher et al 1989b, 1996, Love et al 1991). These side-effects occur more often

in pre-/perimenopausal women. The most important side-effect of tamoxifen is an increased risk of endometrial cancer, which equates to 80 extra cases per 10,000 women treated with tamoxifen at 10 years. The Early Breast Cancer Trialists' Collaborative Group (EBCTCG) analysing data from 37,000 women demonstrated a two-fold increase in endometrial cancer in women taking tamoxifen for 1–2 years and a four-fold increase in those taking it for 5 years (Anonymous 1998b). Tamoxifen is also associated with an increase in endometrial polyps, ovarian cysts and endometrial hyperplasia (Kedar et al 1994). The overall reduction of risk in developing breast cancer outweighs the risk of developing endometrial cancer. In postmenopausal women, tamoxifen increases bone mineral density of the axial skeleton; however, in premenopausal women, there may be a decrease in bone density (Love et al 1992, Kristensen et al 1994, Powles et al 1996). Tamoxifen has been shown to reduce total cholesterol and low-density lipoproteins, which explains the reduction in cardiovascular deaths in those taking tamoxifen (Rutqvist and Mattsson 1993, Costantino et al 1997).

Aromatase inhibitors

Aromatase inhibitors (AIs) significantly reduce oestrogen production in postmenopausal women by inhibiting aromatase, a cytochrome P-450 enzyme found in adipose tissue, liver, muscle, the brain and breast cancer tissue (Miller 2003b). In premenopausal women, AIs are ineffective as they produce an increase in gonadotrophin secretion, which results in reduced feedback of oestrogen on the pituitary and hypothalamus. AIs present an alternative to tamoxifen for antagonizing oestrogenic effects on the breast in postmenopausal women. In the 1990s, third-generation AIs were developed which included two subgroups: a steroidal analogue exemestane, which binds irreversibly to aromatase and is an enzyme inactivator (type 1 inhibitor); and non-steroidal inhibitors that bind reversibly to the haem group of the enzyme (type 2 inhibitor), of which the main agents are anastrozole and letrozole.

Two randomized trials compared initial adjuvant therapy with tamoxifen with an AI. The Arimidex, Tamoxifen Alone or Combination (ATAC) trial showed a significantly improved disease-free survival, time to recurrence and incidence of contralateral breast cancer for arimidex compared with tamoxifen (median follow-up 68 months) (Baum et al 2002, 2003, Howell et al 2005). There were significantly fewer disease recurrences in the arimidex group, but no difference was seen in overall survival. Similar results were seen in the Breast International Group (BIG) 1-98 study comparing letrozole with tamoxifen upfront (Thurlimann et al 2005). In both the ATAC and BIG 1-98 studies, more fractures, fewer thromboembolic events and fewer endometrial cancers were seen in those taking an AI compared with tamoxifen.

A number of trials have looked at sequential endocrine treatment (tamoxifen → AI) including Arimidex, Tamoxifen Alone or together (ATAC), Mayo Clinic-17 (MA-17), the Intergroup Exemestane Study (IES), Arimidex-Nolvadex-95 (ARNO-95) and Austrian Breast and Colorectal Cancer Study Group (ABCSG) (Goss et al 2003, 2005, Coombes et al 2004, Boccardo et al 2005, Howell et al 2005, Jakesz et al 2005). The IES showed a 24% improvement in disease-

free survival in women taking tamoxifen for 2–3 years followed by exemestane compared with 5 years of tamoxifen (Coombes et al 2004). This trial demonstrated an improvement in overall survival in the sequential group, which was significant in the node-positive patients. These trials clearly demonstrate an improvement in disease-free survival, and ASCO advises that AIs should be part of the adjuvant treatment of early-stage breast cancer in postmenopausal women.

AIs have a different side-effect profile compared with tamoxifen; these include hot flushes, vaginal dryness, musculoskeletal pain and headache. AIs are not associated with an increase in thromboembolic disease or endometrial carcinoma, but are associated with an increase in bone fractures and osteoporosis (BIG 1-98 and ATAC trials). Bone monitoring, using dual energy X-ray absorptiometry scanning, should be available for patients taking AIs. All women that start an AI should be advised about calcium and vitamin D supplementation, smoking cessation and the importance of exercise (Hillner et al 2003). It is advised that bone mineral density should be obtained at baseline and monitored annually for all women taking an AI. The Zometa/Femara Adjuvant Synergy trial suggests that treatment with a bisphosphonate at initiation of an AI may prevent a decline in bone health (Brufsky et al 2005).

Faslodex (Fulvestrant or ICI 182,780)

Faslodex is a pure steroidal antioestrogen that binds with 100 times greater affinity to ERs than tamoxifen (Wakeling and Bowler 1992, Rajah et al 1996). It is licensed for use in postmenopausal women with hormone-receptor-positive advanced breast cancer failing on prior antioestrogen therapy. It has a distinct mechanism of action, differing from that of tamoxifen or the AIs, which may help to delay the development of resistance.

Ovarian ablation

There are many methods for suppressing ovarian function in premenopausal women, including surgical oophorectomy, radiation-induced ovarian ablation and gonadotrophin-releasing hormone (GnRH) agonists. GnRH agonists are increasingly being used to achieve ovarian suppression. They overstimulate and subsequently downregulate GnRH receptors. Their effect is to produce an initial rise in luteinizing hormone and follicle-stimulating hormone in the first 7–10 days of treatment, followed by a decrease after 14–21 days that leads to postmenopausal oestrogen and progesterone levels (Williams et al 1986, Cockshott 2000). After 7.3 years of follow-up, the Zoladex Early Breast Cancer Research Association (ZEBRA), randomizing 1640 lymph node-negative, premenopausal ER-positive women, demonstrated no difference in disease-free survival, overall survival or quality of life between the GnRH agonist goserelin (Zoladex) and cyclophosphamide, methotrexate and 5-fluorouracil (CMF) chemotherapy (Jonat et al 2002, Kaufmann et al 2003). A number of trials are investigating the role of GnRH agonists in adjuvant treatment of premenopausal, early-stage breast cancer — Suppression of Ovarian Function Trial (SOFT), Tamoxifen and Exemestane Trial (TEXT), and the Premenopausal Endocrine Responsive Chemotherapy (PERCHE) trial.

Raloxifene

Raloxifene, initially studied as an osteoporotic drug, is a second-generation SERM that has oestrogen antagonist properties on the breast and endometrium, and oestrogenic effects on lipid metabolism, bone and blood clotting. The Multiple Outcomes of Raloxifene Evaluation (MORE) trial confirmed a significant reduction in vertebral fractures in patients taking raloxifene, and as a secondary outcome reduced the incidence of breast cancer in ER-positive patients by 90% but had no effect on ER α -negative patients (Cumming et al 2002). The prospective, randomized controlled Study of Tamoxifen and Raloxifene (STAR) showed no significant difference in the incidence of invasive breast cancer in either group after 3.2 years; however, fewer uterine cancers were reported in the raloxifene group (not statistically significant) (Vogel 2009).

Targeted Therapies

Systemic therapies for breast cancer classically belonged to one of two categories: cytotoxic chemotherapy or hormonal therapy. Recently, a third category, biological/targeted therapy, has emerged. Targeted therapy is a type of medical therapy which blocks the growth of cancer cells by interfering with specific targeted molecules needed for carcinogenesis and tumour growth.

Targeting the epidermal growth factor receptor

The human EGFR-2 (HER-2)/neu (c-erbB-2) gene is localized to chromosome 17q and encodes a family of four transmembrane tyrosine kinase receptor proteins which are members of the EGFR or HER family (Ross et al 2003). These receptor tyrosine kinases provide a binding site for various ligands or proteins, which in turn activate downstream signalling pathways which are essential for cell proliferation and survival. Overexpression of the HER-2 protein occurs in 20–25% of breast cancers and is associated with a worse prognosis (disease-free survival and overall survival) (King et al 1985a, Slamon et al 1987, 1989). The most commonly used test for determining HER-2 protein overexpression is an immunohistochemical (IHC) assay scored from 0 to +3, with 0/+1 representing negative, +2 weakly positive and +3 positive. HER-2 can be measured quantitatively by fluorescence in-situ hybridization (FISH), which provides a direct measure of gene amplification (Perez et al 2002, Hicks and Tubbs 2005). FISH is currently the gold standard for evaluating HER-2 overexpression, and provides the best correlation with clinical response to trastuzumab. IHC3+ correlates well with FISH positivity, but only 20–24% of IHC2+ tumours are also FISH positive (Owens et al 2004).

A new method, chromogenic in-situ hybridization (CISH), has been approved by the US Food and Drug Administration for determining HER-2 status, as an alternative to FISH. CISH has several advantages over FISH in that it produces cheaper and permanent staining, allowing samples to be archived indefinitely (FISH signals are labile and fade over time). CISH is based on bright field microscopy and does not require an expensive fluorescence microscope with

multiband pass filters. It allows concurrent analysis of morphological features of the tumours/cells and gene copy numbers, making the identification of components of interest easier. Tumour heterogeneity can be readily identified at low magnification (Tanner et al 2000, Zhao et al 2002, Arnould et al 2003).

Trastuzumab (Herceptin), a monoclonal antibody that targets HER-2, achieves tumour regression in some patients with HER-2-positive metastatic breast cancer (mBC). Patients with mBC taking trastuzumab in combination with chemotherapy have a longer time to progression (7.4 vs 4.6 months), a higher objective response rate (50% vs 32%), and a longer survival (25.2% vs 20.3%) than chemotherapy alone (Slamon et al 2001). A number of trials have been conducted investigating the role of trastuzumab in the adjuvant setting for HER-2-positive breast cancer. The Herceptin Adjuvant (HERA) trial compared 1–2 years of adjuvant trastuzumab with observation in HER-2-positive women who had completed adjuvant or neoadjuvant chemotherapy, surgery and/or radiotherapy (Piccart-Gebhart et al 2005). Analysis revealed a significant improvement in disease-free survival and overall survival in those taking trastuzumab, and this has become the standard of care for patients with HER-2-positive breast cancer.

Clinical benefit and response rates depend on the intensity of HER-2 overexpression (2+ or 3+), with response rates of 35% seen in grade 3+ but only minimal benefit seen in grade 2+ (Vogel et al 2002). Trastuzumab is well tolerated with side-effects including hypersensitivity and cardiotoxicity; the incidence of class III/IV congestive heart failure ranges from 0.4% to 3.8% (Adamo et al 2007, Anonymous 2008, Perez 2008).

Pertuzumab is a monoclonal antibody that prevents the formation of heterodimers between HER-2 and other members of the HER family (Nahta et al 2004). Pertuzumab localizes to a different domain of the HER-2 protein than trastuzumab. A synergistic interaction between pertuzumab and trastuzumab is being explored.

Dual tyrosine kinase inhibition

Lapatinib is an orally active dual erbB-1/2 tyrosine kinase inhibitor that blocks signalling of both epidermal growth factor (EGFR/erbB-1) and HER-2/neu (erbB-2). Lapatinib binds reversibly to the cytoplasmic ATP-binding site of the kinase and blocks receptor phosphorylation and activation, thereby preventing subsequent downstream signalling events, namely simultaneous activation of extracellular signal-related kinase-1/2 and phosphatidylinositol 3-kinase/Akt.

Lapatinib is active in refractory mBC patients and as a first-line metastatic treatment, with potential benefit in patients with brain metastases. Efficacy of lapatinib has been demonstrated in combination with capecitabine in patients with refractory erbB-2-overexpressing breast cancer (Geyer et al 2006). Lapatinib appears to have either very low or no incidence of cardiotoxicity. The most frequently reported adverse events include nausea, fatigue, itching, rash, diarrhoea, acne and dry skin. There are a number of ongoing phase III trials evaluating the role of lapatinib in the adjuvant setting, including the Tykerb Evaluation After Chemotherapy (TEACH) trial (Moy and Goss 2006).

Targeting the vascular endothelial growth factor pathway

Metastasis of all solid tumours requires angiogenesis (formation of new blood vessels). A number of agents have been developed that target the vascular endothelial growth factor (VEGF) pathway. Breast cancers that overexpress VEGF have a worse disease-free survival and overall survival. Bevacizumab (Avastin) is a human monoclonal antibody that recognizes all isoforms of VEGF-A. In the metastatic setting, bevacizumab has been shown to significantly increase response rates and progression-free survival when given in combination with paclitaxel (E2100 and Avastin and Docetaxel (AVADO) trials) (Miller 2003a, Miles et al 2008, Baar et al 2009). The Ribbon 1 and Ribbon 2 studies are currently investigating the combination of bevacizumab with a number of standard chemotherapy regimens for mBC.

Other targeted therapies

Other targeted therapies currently being evaluated include sunitinib (SU11248), an oral tyrosine kinase inhibitor which blocks a number of signalling pathways including VEGF receptor, platelet-derived growth factor receptor, kit and flt-3 (Miller and Burstein 2005). Rapamycin is an antibiotic that has demonstrated antitumour activity through cell cycle arrest resulting from inhibition of mammalian target of rapamycin (mTOR). Temsirolimus (CCI-779), an mTOR inhibitor, inhibited the proliferation of breast cancer cell lines in preclinical studies but has not entered routine clinical use (Yu et al 2001, Campbell et al 2004). Overexpression of insulin-like growth factor-1 receptor (IGF-1R) is associated with a poor prognosis and resistance to a number of therapies, including hormonal therapy and trastuzumab (Nahta et al 2005). A number of therapies are targeting IGF-1R, including the small molecule tyrosine kinase inhibitor (BMS-536924; Bristol-Myers Squibb) and monoclonal antibodies (CP-751,871; Pfizer).

Adjuvant Chemotherapy

Systemic chemotherapy has been an important part of the adjuvant treatment strategy for many women with early-stage breast cancer since reports of improved outcomes with single-agent chemotherapies following radical mastectomy in the 1970s. The recommendation for the use of chemotherapy is made within a multidisciplinary setting, and is supervised by a clinical or medical oncologist. The efficacy of each treatment is balanced against its specific toxicity profile. Chemotherapy is used primarily in the adjuvant setting for women thought to be at high risk of systemic disease; however, it is now being used increasingly in the neoadjuvant setting. Neoadjuvant chemotherapy is used in patients with large breast cancers to avoid mastectomy and is also the standard of care for inflammatory breast cancer.

Combination chemotherapy has a more prolonged benefit than single-agent chemotherapy, and is usually given in six cycles over a period of 4–6 months. The first adjuvant chemotherapy for breast cancer (CMF) was developed in the late 1970s, and was the mainstay of treatment for many years, significantly reducing risk of recurrence and death (Bona-

donna et al 1976, 1985, Anonymous 1998a). CMF had a significant effect regardless of ER status, tamoxifen use and nodal status, but was influenced by age and menopausal status. Recent meta-analyses have confirmed the benefit of combination chemotherapy over monochemotherapy, with a greater benefit seen in younger patients (Anonymous 2005). For women under 50 years of age, chemotherapy significantly improved 10-year survival by over 10% for those with node-positive disease (53% vs 42%) and by 6% for those with node-negative disease (78% vs 71%). The National Cancer Institute of Canada MA.5 study confirmed the superiority of anthracyclines [six cycles of 5-fluorouracil, epirubicin, cyclophosphamide (FEC)] over CMF, and now anthracycline-based chemotherapy regimens are the standard of care (Levine et al 1998). The potential importance of taxanes (either paclitaxel or docetaxel) as adjuvant chemotherapy is emphasized by a large number of trials (Cancer and Leukemia Group (CALGB) 9344, National Surgical Adjuvant Breast and Bowel Project (NSABP) B-28, Breast Cancer International Research Group (BCIRG) and PACS01) (Henderson et al 2003, Mamounas et al 2003, Martin et al 2003). This body of evidence now supports the use of taxanes in high-risk women in the adjuvant setting (Goldhirsch et al 2005).

Neoadjuvant Medical Therapy

Neoadjuvant (preoperative) therapy is used increasingly with the major aim being to downstage large tumours, thereby avoiding mastectomy and allowing BCS to be performed. This has also enabled earlier assessment of chemosensitivity versus identification of patients with resistant disease. Several studies have documented the finding that response in the breast correlates with survival, demonstrating that downstaging is an excellent surrogate for systemic effectiveness. The decision to proceed with neoadjuvant chemotherapy is associated with several special considerations involving the pretreatment/diagnostic phase (percutaneous needle core biopsy preferable), preoperative planning (insertion of radio-opaque clips to mark the tumour bed prior to completion of chemotherapy; careful imaging to determine the extent of disease), and final surgical decision making (preoperative imaging in order to decide between lumpectomy and mastectomy).

Neoadjuvant endocrine therapy

The use of primary tamoxifen in older women as an alternative to surgery has demonstrated short-term tumour regression but unsatisfactory long-term local control (Cheung et al 2000). Higher response rates have been seen in older women treated with neoadjuvant anastrozole, letrozole and exemestane compared with tamoxifen. Letrozole is currently the only AI licensed for use in the neoadjuvant setting.

Neoadjuvant chemotherapy

Neoadjuvant chemotherapy has significant activity in early breast cancer, with overall objective response rates of 70–90%, which is higher than response rates seen in patients with metastatic disease. Complete remission rates of approximately 20% are seen in patients receiving neoadjuvant chemotherapy (Smith and Lipton 2001).

Triple-Negative Breast Cancers

These are defined as the 10–15% of breast cancers (an increasing percentage of which occur in premenopausal African and African-American women) which do not express the ER, progesterone receptor (PgR) or erb-B2 receptor (Slamon et al 1989, Konecny et al 2003, Carey et al 2006, Dawood et al 2009). This disease is resistant to existing targeted treatments and hormonal therapies, and associated with a high risk of local and systemic relapse (van de Rijn et al 2002, Abd El-Rehim et al 2004, 2005, Foulkes et al 2004, Nielsen et al 2004). These tumours are often poorly differentiated, the majority of which are in the basal group of breast cancers. This basal group stains positively for the basal cell cytokeratins 5/6 and 17, has an increased proliferative rate, develops central necrosis, and does not stain for ER α , PgR or HER-2 receptors (Livasy et al 2006).

Limited clinical data suggest that these cancers are chemosensitive, although it is unclear which regimen provides the best response rates. Triple-negative breast cancers often overexpress EGFR, and as a result may be targeted by EGFR-directed antibodies such as cetuximab or inhibitors of receptor phosphorylation such as gefitinib and erlotinib (Mendelsohn and Baselga 2006). The efficacy of cetuximab alone or in combination with carboplatin is being investigated in the metastatic setting. Other therapies such as

imatinib, lapatinib, dasatinib, poly (ADP-ribose) polymerase inhibitors, survivin inhibitors and pertuzumab are being evaluated in the treatment of this subgroup of breast cancers (Agus et al 2005, Burris et al 2005, Modi et al 2005).

Prognostic Factors

Adjuvant systemic therapy is an important component of breast cancer treatment, aiming to extend disease-free survival and overall survival. When considering which patients are suitable for treatment, systemic risk is assessed based on a number of prognostic factors (Box 47.1).

The Nottingham Prognostic Index (NPI) was developed in 1982 as an aid to the management of breast cancer. By using multivariate analysis, three factors were found to be significant: tumour grade, number of lymph nodes involved and size of the tumour. NPI is calculated using the following formula:

$$\text{NPI} = \text{pathological tumour size (cm)} \times 0.2 + \text{lymph node stage (1,2,3)} + \text{histological grade (1,2,3)}$$

where lymph node stage is scored 1 (no nodes affected), 2 (up to three glands affected) or 3 (more than three glands affected); and tumour grade is scored 1 (for grade I), 2 (for grade II) or 3 (for grade III). Cut-off points of 2.4, 3.4, 4.4, 5.4 and 6.4 are used to divide the patients into six prognostic

Box 47.1 Prognostic factors in breast cancer

Axillary lymph node status

Involvement of local and regional lymph nodes is one of the most important prognostic factors in breast cancer (Galea et al 1992). The 10-year survival reduces from 75% to 25–30% in women with nodal involvement compared with women with no nodal involvement, and the greater the number of nodes, the worse the prognosis (Neville et al 1992). Metastatic involvement to a higher axillary level, particularly those in the apex, carries a worse prognosis (Bedwani et al 1981, Rosen and Groshen 1990).

Tumour size

Smaller tumours (<15 mm) have been shown to have a 'better prognosis' than larger tumours (>15 mm), with a risk of axillary lymph nodal involvement of 40% compared with 12–20%, respectively (Carter et al 1989, Henson et al 1991, O'Dwyer 1991, Galea et al 1992, Neville et al 1992).

Differentiation

Juan Hassiman was the first to suggest a correlation between the microscopic appearance of tumours and their degree of malignancy in the 19th century (Carstens et al 1985). Certain types of invasive breast cancer (tubular, mucinous, cribriform, medullary and lobular) carry a more favourable prognosis than invasive cancer of no special type (Carstens et al 1985, Eichhorn 2004, Sullivan et al 2005, Gatti et al 2006, Tan et al 2008, Contreras and Sattar 2009). Bloom and Richardson (1957) developed a numerical grading system assigned by pathologists to invasive breast cancers. It is the most common type of cancer grading system currently used, based on three morphological features of invasive breast cancers: (1) the degree of tumour tubule formation (percentage cancer composed of tubular structures); (2) the mitotic activity of the tumour (rate of cell division); and (3) the nuclear pleomorphism of tumour cells (nuclear grade, change in cell size and uniformity). Each of these features is assigned a score

ranging from 1 to 3. The scores are then added together for a final score ranging from 3 to 9. This value is then used to grade the tumour as follows: 3–5, grade 1 tumour (well differentiated); 6–7, grade 2 tumour (moderately differentiated); and 8–9, grade 3 tumour (poorly differentiated).

Lymphovascular invasion

The presence of lymphovascular invasion closely correlates with local and regional lymph node involvement (Ejlertsen et al 2009).

ER /PgR status

A response to endocrine therapy is seen in 50–60% of patients with ER α -positive tumours, compared with a minimal response seen in ER α -negative patients (Horwitz and McGuire 1975, Hunt 2001). In patients with ER α -/PgR-positive tumours, the response rate increases to 78%.

Histopathology of BRCA1 mutations

Cancers associated with *BRCA1* mutations have a significantly higher mitotic rate, are less likely to be ER α -/PgR-positive, more aneuploid and have greater lymphocytic infiltration than sporadic cancers (Marcus et al 1996, Anonymous 1997b, Karp et al 1997, Armes et al 1998, Robson et al 1998).

Expression of growth factor receptors

Expression of EGFR is inversely correlated with ER α positivity, and therefore may be associated with endocrine resistance (Nicholson et al 1994). Slamon et al (1987) showed that *HER-2* gene amplification independently predicted poorer overall survival and disease-free survival in a multivariate analysis in node-positive patients. Larger tumour size and higher grade (poor prognostic factors) have been also correlated with *HER-2* overexpression (Rilke et al 1991, Pietras et al 1995).

groups (excellent, good, moderate I and II, poor and very poor), giving 10-year survival rates of 96%, 93%, 82%, 75%, 53% and 39%, respectively.

Genomics and Proteomics

Genomics (study of the human genome) and proteomics (analysis of the protein component of the gene) are two branches of molecular biology that will have a major role in understanding, diagnosing and potentially providing therapeutic targets in breast cancer. Gene expression cDNA arrays in the landmark study by Perou et al identified five distinct gene expression patterns — two ER α -positive groups referred to as luminal subtypes (A and B) as they share features with luminal epithelial cells arising from the inner layer of the duct lining, another group that overexpresses HER-2, and a normal breast gene expression group characterized by elevated expression of basal epithelial cell genes and reduced expression of basal epithelial cell genes (Perou et al 2000). The final group was a basal-like subgroup which shares features with normal basal epithelial cells (ER α , PgR and HER-2 negative). cDNA arrays have also distinguished cancers associated with *BRCA1/BRCA2* mutations, ER α expression and prognostic subgroups in node-negative breast cancer. In the future, it is envisaged that gene expression profiles may guide decisions on the choice of adjuvant therapy for individual patients. Proteomics has already assumed a role in the monitoring of response and prediction of both resistance and relapse in patients treated with novel targeted therapies (van de Vijver et al 2002, McClelland and Gullick 2003).

Micrometastases in Breast Cancer

Disseminated tumour cells (DTCs) in the bone marrow of breast cancer patients are an independent predictor of poor prognosis. A number of studies have detected DTCs in 13–42% of patients without overt distant metastases (stage M0) (Schlimok et al 1987, Cote et al 1991, Harbeck et al 1994, Diel et al 1996, Molino et al 1997, Mansi et al 1999, Braun et al 2000b, Gebauer et al 2001, Gerber et al 2001, Wiedswang et al 2003, Braun et al 2005). The prognostic relevance of detecting DTCs has an impact on breast-cancer-specific survival, disease-free survival, distant disease-free survival and overall survival. In one multivariate analysis, bone marrow status was the most important independent factor for disease-free and overall survival. Several studies have shown that the presence of DTCs in bone marrow following adjuvant therapy is a predictor of poor prognosis (Braun et al 2000a, Wiedswang et al 2004, Janni et al 2005). Bone marrow analysis of high-risk patients (more than three involved axillary nodes), before and after receiving adjuvant taxane or anthracycline therapy, demonstrated that the presence of tumour cells was associated with an extremely poor prognosis and a heterogeneous response to treatment (Braun et al 2000a).

Circulating tumour cells (CTCs) are defined as micrometastases detected in peripheral blood. CTCs have been detected in 10–60% of primary breast cancer patients with no signs of overt metastases, depending on the detection

technique used (Kraeft et al 2000, Witzig et al 2002). Several studies have used CTCs as a tool to assist breast cancer diagnosis (Reinholz et al 2005, Chen et al 2006). The majority of studies reporting on the prognostic significance of CTCs in patients with mBC use the Cell-Search (Veridex LLC) system. The presence of more than five CTCs per 7.5 ml of whole blood in patients with mBC before a new treatment was an independent predictor of overall survival and progression-free survival (Cristofanilli et al 2004). The presence of CTCs was also shown to be a better surrogate endpoint than current radiological imaging for assessing response to treatment (Budd et al 2006). The Southwest Oncology Group has launched a phase III trial (NCT00382018) evaluating a change in chemotherapy regimen in those mBC patients with elevated CTCs following the first follow-up assessment.

It is likely that the future role of minimal residual disease (DTCs/CTCs) will increase in the diagnosis, prognosis and treatment decision making of breast cancer patients.

Gene Expression Signatures

Decisions for treating patients with adjuvant therapy in locally advanced breast cancer have relied on assessing both patient-related and tumour-related prognostic markers providing valuable information on risk of relapse. Through use of gene expression microarray technology, studies in gene expression profiling have improved upon these traditional prognostic tools and enabled a risk prediction for an individual patient.

Gene expression signatures as predictors of recurrence

In the top-down approach, a gene expression signature is derived by seeking profiles that are correlated with clinical outcome without a previous biological assumption (Loi et al 2005).

The 70-gene prognostic signature (MammaPrint)

The Netherlands Cancer Institute in Amsterdam and Rossetta were the first to conduct a comprehensive genomewide assessment of gene expression identifying broadly applicable prognostic markers. This signature outperformed the St Gallen and National Institutes of Health criteria in being the strongest predictor for distant metastases free survival, independent of adjuvant treatment, tumour size, grade and age in both node-positive and node-negative patients. These findings suggest that MammaPrint could potentially increase the detection rate of those patients with a good prognosis, thereby decreasing the use of chemotherapy in these patients. In 2007, the US Food and Drug Administration cleared the MammaPrint test for use for node-negative breast cancer patients under 61 years of age with small tumours (<5 cm).

The Microarray In Node-negative Disease may Avoid Chemotherapy Trial (MINDACT) (EORTC 10041/BIG 03/04) is evaluating the gene expression signature MammaPrint. This trial is setting out to see whether it may be possible to distinguish between patients with a high risk of

developing metastatic disease and patients who could be spared chemotherapy as their distant metastases risk is low so adjuvant chemotherapy would offer minimal benefit (Cardoso et al 2008). The trial is enrolling node-negative breast cancer patients who will have their risk assessed through both traditional clinicopathological factors (using Adjuvant Online; <http://www.cancerscreening.nhs.uk/breastscreen/index.html>) and MammaPrint. If the main hypothesis of the MINDACT is validated, it will be the first study to provide level I evidence for a decrease in the indications of adjuvant chemotherapy.

The 76-gene prognostic signature

Using a different microarray platform (Affymetrix), the Erasmus Medical Centre, Rotterdam in collaboration with Veridex LL identified a 76-gene prognostic signature that could be used to predict the development of distant metastases within 5 years in node-negative primary breast cancer patients ($n = 15$, irrespective of age and tumour size) who did not receive systemic treatment. Independent validation of both the 70-gene and 76-gene prognostic signatures has been conducted by TRANSBIG, a Translational Research Network associated with the Breast International Group.

Oncotype DX

Several signatures have been generated to predict prognosis in patients treated with endocrine therapy. Paik et al, in collaboration with Genomic Health Inc., developed a recurrence score based on 21 genes that appeared to accurately predict the likelihood of distant recurrence in tamoxifen-treated patients with node-negative, ER-positive breast cancer (Paik et al 2004). The process of clinical validation to achieve level I evidence is ongoing for Oncotype DX in the clinical trial TAILORx [Trial Assigning Individualized Options for Treatment (Rx)]. This trial will evaluate whether women with node-negative, ER α -positive breast cancer need chemotherapy based on their recurrence score. The US Intergroup launched the trial in May 2006 and is expected to accrue over 10,000 patients, of which 29% will be low risk, 44% intermediate risk and 27% high risk.

In the bottom-up approach, a set of genes is generated from specific biological assumptions of cellular mechanisms, before being correlated with clinical outcome to assess relevance.

Wound-response signature

Chang et al derived a wound-response signature with prognostic potential by examining the processes involved in wound healing and then drawing similarities with the oncogenic process (Chang et al 2004).

Invasiveness gene signature

Lui et al generated a 186-gene 'invasiveness' signature (IGS) by using gene expression profiling of tumorigenic breast cancer cells compared with normal breast epithelium (Liu et al 2007). The IGS is significantly associated with overall and metastases-free survival independent of established pathological and clinical variables.

Gene expression signatures as predictors for drug sensitivity

Some gene signatures have been developed to identify patients who are sensitive to specific therapies; this is known as 'pharmacogenomics'. Markers predicting treatment response could ultimately lead to individualization of adjuvant therapy.

Gene signatures clearly represent a major step forward in the molecular prediction of drug sensitivity and patient outcomes. Trials such as MINDACT and TAILORx are still required to prove that clinical benefit can be derived from this new technology. This shift in emphasis towards molecular profiling represents a significant revolution in the management of breast cancer patients. It is likely that gene expression profiles will become part of an integrated decision-making model, but for the time being, the treatment guidelines of the National Comprehensive Cancer Network, National Institutes of Health and St Gallen will continue to be used.

Adjuvant Online

(<http://www.adjuvantonline.com>)

'The purpose of Adjuvant is to help health professionals and patients with early cancer discuss the risks and benefits of getting additional therapy (adjuvant therapy: usually chemotherapy, hormone therapy, or both) after surgery. The goal is to help health professionals make estimates of the risk of negative outcome (cancer-related mortality or relapse) without systemic adjuvant therapy, estimates of the reduction of these risks afforded by therapy, and risks of side-effects of the therapy. These estimates are based on information entered about individual patients and their tumours (e.g. patient age, tumour size, nodal involvement, histological grade, etc.) These estimates are then provided on printed sheets in simple graphical and text formats to be used in consultations.'

Metastatic Breast Cancer

Although survival from breast cancer has been improving, approximately 40% of women with early-stage breast cancer will develop metastatic disease. Median survival time following relapse is 18–24 months, but many live for several years and a few for a decade or more. The treatment of mBC patients is to prolong life, maintain a good quality of life and relieve symptoms. The goals for treatment are dependent upon a number of variables including patient-related factors such as comorbidities and age, and tumour related factors including hormone receptor status, tumour grade and site of metastasis. The recommended radiological tests routinely employed in the staging work-up for mBC include bone scintigraphy and contrast-enhanced CT of the chest, abdomen and pelvis (Figures 47.10 and 47.11). Treatment options include endocrine therapy with tamoxifen, AI, GnRH analogues and chemotherapy. Approximately 50% of patients achieve tumour regression with duration of less than 1 year.

Figure 47.10 Bone scan breast metastases. Multiple areas of increased activity (black) are due to multiple bone metastases. The bisphosphonates used for bone scanning are labelled with technetium-99m. The tracer is taken up by osteoblasts within the bone.

Chemotherapy in metastatic breast cancer

Studies have shown that 24–30% of women with node-negative breast cancer and 50–60% of those with node-positive disease at diagnosis will relapse (Honig 1996). Approximately 6–10% of patients will present with de-novo metastatic disease at diagnosis (Honig 1996, Cardoso et al 2002). The median survival for women presenting with de-novo mBC is 2–4 years, although an increased survival is seen in a small percentage of patients (Falkson et al 1995, Greenberg et al 1996, Honig 1996). Despite the many new options for the treatment of mBC, mortality rates have only shown a small decline from 1930 to 1998 (1.6% annually from 1989 to 1995, and 3.4% more recently) (Jemal et al 2002).

The chemotherapy regimen selected will depend on previous adjuvant therapies received, and is chosen not just on the basis of efficacy, but also with the aim of minimizing toxicity. Anthracycline-based chemotherapy is well established as the first-line option for women with mBC, when this has not been used previously in the adjuvant setting. Both paclitaxel and docetaxel have been evaluated in mBC after anthracycline use. Recent meta-analysis has shown a significantly increased overall survival, time to progression and response rates in taxane-containing chemotherapy regimens compared with non-taxane-containing regimens.

Figure 47.11 Computed tomography (CT) of liver breast metastases. Contrast-enhanced study of the liver showing lower attenuation of metastases which have not enhanced, like the surrounding liver, with contrast (white arrows). CT allows accurate measurement of metastatic deposits for assessing change in size response to chemotherapy and hormonal therapy regimes.

Combination of the orally bioavailable prodrug capecitabine with docetaxel has shown greater response rates, time to disease progression and overall survival compared with docetaxel alone. Other agents include the semisynthetic vinca alkaloid vinorelbine, gemcitabine and the platinum salts cisplatin and carboplatin. There has been some evidence to suggest that sequential single agents may be equally effective in terms of survival, with reduced toxicity compared with combination chemotherapy. There appears to be little survival benefit in giving chemotherapy for more than 6 months. There is an underlying assumption that improvements in overall response rates translate into long-term survival benefit (Greenberg et al 1996, Fossati et al 1998, Pierga et al 2001, Bruzzi et al 2005).

Trastuzumab in metastatic breast cancer

Trastuzumab is effective in those women with mBC over-expressing HER-2 (only IHC3+ or FISH-positive patients benefit). Slamon et al (2001) were the first to show that addition of trastuzumab to chemotherapy in patients with HER-2-positive mBC was associated with a longer time to progression (7.4 months vs 4.6 months), higher response rate (50% vs 32%) and longer survival (25.1 vs 20.3 months). Combining trastuzumab with docetaxel has shown significantly greater response rates (61% vs 36%) and overall survival (24.1% vs 13.2 months) compared with single-agent docetaxel (Marty et al 2005). The duration of treatment with trastuzumab is unknown; however, this is being addressed by a large randomized study.

Other agents used in metastatic breast cancer

Epithilones are macrolide antibiotics isolated from the myxobacterium *Sorangium cellulosum*, which promote microtubule stabilization via a similar mechanism to that of the

taxanes (Bollag et al 1995, Wartmann and Altmann 2002). Epithilones are associated with a lower susceptibility to drug resistance and greater efficacy in taxane-resistant tumours. Recently, the epithilone ixabepilone (Ixempra, Bristol-Myers Squibb) has been approved for use by the US Food and Drug Administration after having shown activity in chemotherapy-sensitive and chemotherapy-resistant tumour models, and synergistic activity with other chemotherapeutic and targeted agents. Randomized trials in patients with bony metastatic disease have shown that bisphosphonates can significantly reduce skeletal-related events, including pathological fractures, spinal cord compression, hypercalcaemia and the need for intervention with radiotherapy by 30–50%. They have also been shown to reduce bony pain, but have not shown any improvement in survival (Paterson et al 1993, van Holten-Verzantvoort et al 1993, Lipton et al 2000, Rosen et al 2001). The dual tyrosine kinase inhibitor lapatinib has shown significant efficacy in refractory metastatic HER-2-positive breast cancer patients (previously treated with trastuzumab) and as a first-line metastatic treatment, with potential benefit in patients with brain metastases.

Preservation of Fertility in Breast Cancer Patients

Breast cancer is the most common cancer affecting women of reproductive age, and approximately 13% of all breast cancer diagnoses are made in women aged under 45 years (Gloeckler Ries et al 2003). Many breast cancer patients may not have completed their family planning, and may wish to have children after their breast cancer treatment. Options for fertility preserving should be discussed before starting treatment in some patients. Standard regimens of radiation therapy for breast cancer do not affect the ovaries significantly; however, internal scatter radiation can reach the pelvis and ovaries. As a result, in-vitro fertilization (IVF) and egg harvesting should not be performed during treatment and pregnancy should be prevented (Arnon et al 2001, Falcone et al 2004, Jeruss and Woodruff 2009). Indirect evidence supports a delay of antioestrogen treatment to allow for pregnancy after surgery and radiotherapy are completed (Gradishar and Hellmund 2002, Goss 2007). As a result, the threat to fertility for a patient not receiving chemotherapy, whose baseline fertility is within the normal range, is small. Breast cancer treatments are well known to affect menstrual status and fertility among premenopausal women diagnosed with breast cancer (Lobo 2005). Amenorrhoea following systemic breast cancer treatment may result in loss of fertility, onset of menopausal symptoms, problems with sexual functioning, and exposure to the long-term health risks of an early menopause.

Risk of chemotherapy-related amenorrhoea and menopause

The risk of chemotherapy-related amenorrhoea depends on the patient's age, the type of chemotherapeutic agents used and the total dose administered. Older women have a higher incidence of complete ovarian failure and permanent infertility compared with younger women (Minton and Munster 2002, Maltaris et al 2007). This higher incidence is explained

by the greater primordial follicle reserve (ovarian reserve) in younger women, which decreases with age. The degree of damage will determine whether the amenorrhoea is permanent or temporary; should no oocytes remain viable, menses may cease altogether and menopause will follow. Menstrual function may resume months or occasionally years after treatment; however, the majority of women who remain amenorrhoeic 1 year after treatment will not regain ovarian function. Assessment of the ovarian reserve in patients treated with chemotherapy includes serum measurements of anti-Müllerian hormone, follicle-stimulating hormone, inhibin B and oestrogen levels (Lutchman Singh et al 2007, van Beek et al 2007). An ultrasound-guided antral follicle count can also be useful for assessing ovarian reserve (Lutchman Singh et al 2007).

Chemotherapy can cause ovarian damage by a number of mechanisms. Dividing cells are vulnerable to most cytotoxic agents; however, alkylating agents such as cyclophosphamide present the greatest potential for ovarian failure among all chemotherapeutic agents (Meirow 1999). Alkylating agents are not cell cycle specific and may affect cells not actively dividing, including the pregranulosa cells of the primordial follicles and oocytes. The higher the cumulative dose of cyclophosphamide, the greater the observed incidence of menopause. It has been reported that with the classic CMF regimen, the incidence of amenorrhoea was 61% in women under 40 years of age and 95% in women over 40 years of age (Goldhirsch et al 1990). The regimen of six cycles of FEC induces menopause in 60% of patients (Venturini et al 2005). A prospective cohort study evaluating 595 women aged 25–40 years treated for early breast cancer with a number of different chemotherapy regimens showed that menstrual cycles were more likely to persist in women treated with regimens containing less cumulative cyclophosphamide (Petrek et al 2006). Those patients on a CMF regimen were more likely than women on other regimens to bleed within the first month of chemotherapy, but were less likely to commence menses 1 year later. The study also showed that tamoxifen accounted for a 15% decrease in menstrual cycling at 1 and 2 years, regardless of chemotherapy regimen. Most premenopausal women will continue to menstruate whilst taking tamoxifen, although their menses may become irregular. One study has shown no effect of trastuzumab on fertility (Abusief et al 2006).

Strategies to preserve fertility in women with breast cancer

The ASCO and UK National Health Service guidelines recommend that the implications of oncological treatment for fertility should be discussed with patients. If sufficient time exists before a woman is about to start chemotherapy or radiotherapy, she may undergo IVF to cryopreserve embryos or an embryo (Falcone et al 2004, Roberts and Oktay 2005, Agarwal and Chang 2007, West et al 2007). This technique requires a delay in cancer treatment for up to 1 month, which may not be an option for some patients. Cryopreservation remains the most effective approach to preserve fertility; however, post-thaw survival rates of embryos are in the range of 35–90%, and implantation rates are between 8% and 30%. If multiple embryos are available, cumulative

pregnancy rates can be more than 60% (Seli and Tangir 2005). Delivery rates per embryo transfer using cryopreserved embryos are in the range of 18–20%. This approach requires IVF and a male partner.

Oocyte banking is more difficult than embryo cryopreservation, as oocyte cooling and exposure to cryopreservation agents affects the cytoskeleton and causes hardening of the zona pellucida. The success is dependent upon the number of eggs harvested (<10 oocytes = very low chance of pregnancy). The overall livebirth rate per preserved oocyte is approximately 3%, which is much lower than that for IVF using fresh oocytes (Gosden 2005). Several studies are evaluating the use of GnRH analogues to preserve ovarian function during cytotoxic treatment. Research in a population of older women of reproductive age has suggested that addition of a GnRH analogue to treatment may increase a woman's likelihood of remaining premenopausal after chemotherapy; however, the reproductive outcome was poor (Fox et al 2003).

It has been suggested that IVF could accelerate the disease process in women with ER α -positive breast cancer by increasing the oestrogen concentration. In one study of 100 patients, ovarian stimulation with concurrent administration of an AI or tamoxifen demonstrated no increase in recurrence and no effect on the IVF cycle (Oktay et al 2005, Azim et al 2008). Another technique whereby immature oocytes are collected and matured in vitro, avoiding ovarian stimulation, has been used in women with polycystic ovary syndrome (Lee 2007, Reinblatt and Buckett 2008). Oocyte donation is a well-established form of assisted reproduction, with 20% of replaced embryos resulting in a live birth. The harvesting of ovarian tissue is less established; this involves the removal of the ovarian cortex by laparoscopy, which is cryopreserved for later reimplantation. Only small numbers of women have had thawed ovarian tissue reimplanted, and only five live births have resulted to date (Donnez et al 2004, Meirow et al 2005, Demeestere et al 2007, Andersen et al 2008). The incidence of occult ovarian cancer in *BRCA1/BRCA2* carriers is low, but the potential for development of ovarian cancer in the transplanted tissue makes it a poor option in this subgroup (Colgan et al 2001).

Pregnancy-Associated Breast Cancer

Pregnancy-associated breast cancer (PBAC) is defined as breast cancer diagnosed during pregnancy or lactation or 1 year post partum (Petrek 1991). After cervical cancer, breast cancer is the second most common malignancy in pregnant women (Antonelli et al 1996). The diagnosis is often delayed due to physiological and anatomical changes in the breast, and a low index of suspicion of breast cancer in these patients. The average age of patients with PBAC is 32–38 years. The estimated incidence of PBAC is 0.2–3.8% of all breast cancers, and it is reported to occur in one in 3000–10,000 pregnancies (Anderson 1979, Gemignani et al 1999). Women are three times more likely to have a family history of breast cancer than age-matched, non-pregnant/non-lactating women (Ishida et al 1992). Carriers of the *BRCA1/BRCA2* mutation who have had a full-term pregnancy are more likely to develop breast cancer before 40

years of age than nulliparous women with the *BRCA1/BRCA2* mutation (Jernstrom et al 1999).

PABC often presents as a painless mass, although clinical examination of the breast may be increasingly difficult because of increased nodularity (King et al 1985b, Ribeiro et al 1986). During pregnancy, oestrogen, progesterone, prolactin and chorionic gonadotrophin rise, and the breasts undergo marked ductal and lobular proliferation with blood flow increasing by 180% and weight doubling (Scott-Conner and Schorr 1995). A study of 63 women with PABC showed that less than 20% were diagnosed prior to delivery and the median size of the tumour was 3.5 cm. Sixty-two percent of patients were found to have nodal involvement compared with 39% of matched non-pregnant controls (Petrek 1991). PABC is more likely to present with larger tumours, vascular invasion and distant metastases (Guinee et al 1994).

Between 70% and 80% of breast biopsies performed during pregnancy are benign (Woo et al 2003). A dominant mass presenting during pregnancy must be formally investigated by 'triple assessment'. Mammography during pregnancy is not advised, and ultrasound can identify cystic lesions and help to characterize solid masses (Lieberman et al 1994, Ahn et al 2003). Bone scans for metastatic disease are generally not recommended, and MRI can be used to evaluate liver and bony metastases (Baker et al 1987). PABC tends to present with ER α -/PgR-negative tumours, and appears to have a worse 5-year survival in women presenting with nodal involvement compared with non-pregnant matched controls (47% vs 59%) (Petrek 1991, Bonnier et al 1997). There appears to be an increased relative risk of dying from breast cancer if it develops within 4 years of giving birth, compared with age-matched women who have never been pregnant and who develop breast cancer (Duncan et al 1986, Guinee et al 1994).

Treatment of PABC should not be delayed because of pregnancy. Surgery can be performed during all trimesters of pregnancy with no effect on the fetus. Surgery is tailored to the gestation and the breast cancer stage. BCS is generally not recommended during the first trimester because of the need to delay radiotherapy and an increase in local risk of recurrence. Mastectomy can be performed during all trimesters of pregnancy, although immediate reconstruction is not recommended due to difficulty in achieving symmetry.

Chemotherapy is contraindicated in the first trimester because of an increased risk of spontaneous abortion and a teratogenic risk of 14–19%, falling to 1.4% by the second trimester (Ebert et al 1997). Chemotherapy can cross the placenta and, if given up to 15 weeks of gestation, has been shown to interfere with cell differentiation leading to permanent organ malformation. Administration of FEC chemotherapy during the second and third trimesters in a study of 24 women showed no congenital malformations, although chemotherapy should be stopped 3 weeks before delivery (Berry et al 1999, Keleher et al 2002). Women with node-positive PABC are advised to start chemotherapy after the first trimester. Tamoxifen is associated with an increased risk of congenital malformations and spontaneous abortion, and therefore endocrine therapy is not recommended during pregnancy (Isaacs et al 2001).

The use of radiotherapy in women with PABC poses a particular dilemma. During the first trimester, the fetus is

outside the radiation field of the chest wall but is still exposed to scatter radiation; however, during the later stages of pregnancy, the fetus lies outside the pelvis and is closer to the radiation field, but will have completed organogenesis and the effects of radiation will be reduced (Saunders 2001). There have been anecdotal reports of fetal malformations as well as normal pregnancy outcomes in pregnant women receiving radiotherapy for breast cancer. Therefore, the teratogenic effects of radiotherapy need to be weighed up against the improvement in disease-free survival.

In women with metastatic PABC, the risk for quick treatment must be balanced against the risk to the fetus. No significant difference in survival is seen in women opting to continue pregnancy with an associated breast cancer and those opting for a termination of pregnancy. There is no time interval known to be safe for becoming pregnant after PABC. Some advocate 2 years following treatment for women with 'low-risk' PABC and longer for those with high-risk tumours.

Breast Cancer in the Elderly

Forty percent of breast cancers occur in women over 70 years of age. Historically, these women have been treated by hormone manipulation alone, but local control was frequently unsatisfactory, necessitating surgical intervention or radiotherapy at a later stage. Since the biology of cancers in this age group is similar to that in younger women, the majority of elderly patients presenting with breast cancer should be managed in the standard way. Primary hormonal treatment should be reserved for those women who decline surgical intervention or in whom comorbidity is such that their disease is unlikely to progress significantly within their natural lifetime.

Clinical Follow-Up

Most follow-up protocols are not evidence based and have evolved over time. In practice, the majority of recurrences are detected by patients themselves or by mammography. The aims of follow-up are: (1) early detection of local recurrence, (2) early detection of metastatic disease, (3) screening for new primary breast cancer, (4) detection of treatment-related toxicities, and (5) provision of psychological support. Two-thirds of local recurrences after mastectomy occur in the first 5 years, but after BCS, there is a steady relapse rate. Women with a history of invasive breast cancer have a five-fold increased risk of developing a second primary with an annual risk of contralateral breast cancer of 0.6%.

Patients continuing active treatment should be followed-up until such treatment has been completed. Follow-up should be stratified according to disease, with high-risk patients followed-up more closely with joint care by surgeons and oncologists according to agreed local protocols. Mammography is an important component of follow-up, and the current guidelines from the Royal College of Radiologists advise performing annual mammography for the first 5–10 years.

Breast Reconstruction after Surgery for Breast Cancer

Most healthy patients under the age of 70 years with a non-inflammatory or locally advanced tumour undergoing a skin-sparing mastectomy should be offered immediate breast reconstruction.

The surgical treatment for patients with breast cancer will involve either BCS or mastectomy, both of which will result in considerable asymmetry of the breasts. Improved survival as a result of earlier detection of breast cancers means that women will live for much longer with the psychological problems and physical defects of surgery. Mastectomy affects body image and can lead to depression, anxiety and poor self-esteem. Breast reconstruction offers restoration of breast symmetry to women by creating a breast which is similar in shape, size, contour and position to the opposite breast. It plays a significant role in the women's physical, psychological and emotional recovery from breast cancer.

Breast reconstruction has become an integral part in the management of women with breast cancer. Candidates for breast reconstructive surgery are those who have considerable asymmetry following tumour removal. The majority of reconstructions are performed in patients undergoing mastectomy, and reconstructive options should be discussed prior to surgery. The process of breast reconstruction involves:

- reconstruction of the breast mound (excision of breast tissue results in reduction in breast volume); and
- reconstruction of the skin (using local skin or by transferring skin from a distant site).

Further surgery may involve nipple–areola reconstruction and, in some cases, surgery to the contralateral breast to achieve symmetry. The process of breast reconstruction requires highly motivated surgical staff and patients, as many stages are involved. Skin-sparing mastectomy has significantly improved aesthetic outcomes with breast reconstruction. It allows mastectomy, with preservation of the breast skin and inframammary fold, with breast tissue excised through small skin incisions (Cunnick and Mokbel 2004). This technique produces excellent cosmetic results, particularly when combined with immediate reconstruction.

Breast reconstruction can be performed immediately at the time of mastectomy, or delayed following adjuvant therapy. Immediate reconstruction is advantageous as it results in reduced cost (single operation and hospital stay), superior cosmetic result (surgeon works with good-quality skin that is unscarred and not suffering from the effects of radiotherapy) and reduced psychological morbidity (Kroll et al 1995, Khoo et al 1998, Al-Ghazal et al 2000). The disadvantages of immediate reconstruction include limited time for patient decision making, increased operative time and the detrimental effect that chemotherapy and radiotherapy can have on some types of reconstruction (Kronowitz and Robb 2004). There are no significant differences in survival between immediate and delayed reconstruction. Delayed reconstruction allows the patient unlimited time for decision making, avoids adjuvant therapy delay and

Figure 47.12 (A) Preoperative, (B) intraoperative and (C) postoperative latissimus dorsi (LD) reconstruction. Left breast skin-sparing mastectomy and immediate autologous LD flap breast reconstruction, right mastopexy and left nipple-areola reconstruction with a small local flap and tattoo. Box 47.3 Online breast cancer resources

- www.imaginis.com — an independent American resource providing information and news on breast cancer and related women's health topics.
- www.y-me.org — a charitable, national voluntary health organization set up by breast cancer sufferers.
- www.mskcc.org — website for the Memorial Sloan-Kettering Cancer Center, New York offering a balanced and unbiased overview of the breast reconstruction options available to patients, and addressing the risk-benefit balance of each.
- www.cancerbackup.org.uk — a charitable resource that offers cancer patients and their families up-to-date information, practical advice and support on all cancers, including breast.
- www.cancer.gov — the National Cancer Institute is a component of the US National Institutes of Health, and is the Federal Government's principal agency for cancer research and training. This resource offers information for both medical professionals and patients.
- www.breastcancer.org — a non-profit organization dedicated to providing the most reliable, complete and up-to-date information about breast cancer.
- www.cancer.org — website of the American Cancer Society, a nationwide, community-based health organization dedicated to eliminating cancer as a major health problem and eliminating suffering due to cancer.
- <http://qap.sdsu.edu/> — Cancer Clinical Services Quality Assurance Project and the Center for Health Professional Education and Training (the training centre provides this resource for healthcare providers involved in the early detection of breast and cervical cancers).
- www.breasthealth.com.au — official website of the National Breast Cancer Center, which was set up in 1955 by the Australian Government as a means to support patients and their families through comprehensive information on breast and ovarian cancer.
- www.breastcenter.com — official web page of the Center for Restorative Breast Surgery, founded by Dr Frank DellaCroce and Dr Scott Sullivan.
- www.mayoclinic.com — the official website of the Mayo Clinic has a page dedicated to breast reconstruction.

excludes the detrimental effects of adjuvant therapy. The mastectomy flaps, however, may be thin, scarred and contracted, resulting in a less pleasant aesthetic appearance. There are a number of contraindications to breast reconstruction including non-resectable chest wall disease, progressive systemic disease, patients with significant comorbidities and those felt to be unsuitable psychologically (Box 47.2 and Figure 47.12).

Oncoplastic techniques

A tumour may be excised within an area normally removed during a mastopexy (breast lift) or reduction, thereby achieving wide local excision of the mass and reconstruction of the breast. Symmetry can be achieved by contralateral breast reduction or mastopexy.

Nipple–areola reconstruction

Some patients are content with a prosthetic nipple, but all should have the opportunity to have a nipple–areola reconstruction. This is often performed 6 months after the reconstruction by a number of techniques including nipple sharing and use of local flaps. These procedures can be performed under local anaesthetic, and the areola is now reconstructed with a dermal tattoo using a three-dimensional colour chart to achieve a good colour match.

Online Resources

There are a host of online resources (Box 47.3) with an interest in breast cancer and reconstruction (Leff and Kinross 2007).

KEY POINTS

1. Breast cancer is common and is the cause of significant morbidity and mortality worldwide.
2. The incidence of breast cancer is increasing, but mortality is decreasing.
3. The incidence of breast cancer increases with age.
4. There is a small increased risk of breast cancer diagnosis in women taking HRT, but this needs to be balanced against the benefits of treatment.
5. Familial breast cancer accounts for only 5% of cases and nearly half of these are due to mutations in *BRCA1* and *BRCA2*.
6. Breast cancer may present as symptomatic or screen-detected disease.
7. The diagnosis and management of breast cancer should be undertaken by an MDT of specialists.
8. Diagnosis is based on triple assessment — clinical examination, radiological imaging and cytology/histology.
9. The aim of primary surgical treatment is complete removal and hence control of local disease.
10. DCIS is treated by complete surgical excision. Axillary surgery is not required. The role of adjuvant treatments is uncertain.
11. Women undergoing mastectomy should be offered breast reconstruction.
12. Radiotherapy to the breast is standard after BCS for invasive disease to minimize the risk of local recurrence.
13. Patients with axillary node disease should have axillary clearance or radiotherapy.
14. All ER-positive patients should receive adjuvant tamoxifen for 5 years.
15. Adjuvant chemotherapy is offered to patients deemed to be at high risk of systemic relapse.
16. Metastatic disease is incurable and treatment is palliative.
17. Breast cancer in pregnancy usually presents at a more advanced stage, but the prognosis stage for stage is the same.
18. New hormonal and biological therapies for breast cancer are becoming available.

Introduction

The patient

The aim of this chapter is to identify and discuss the psychological, psychosocial, psychosexual, emotional and practical needs of women affected by a gynaecological cancer. It considers ways in which we can provide care and support to meet the needs of patients and their families throughout their cancer journey. The role of the professional carer, and the knowledge and skills required to assess the individual needs of these women will be explored, and recommendations for practical interventions aimed at providing support will be discussed. These issues affect both cancer survivors and those in the palliative stage of their disease process.

When a woman is diagnosed with gynaecological cancer, it affects her life in many ways. At the time of diagnosis, it may feel like an emotional onslaught and the effects can be both abrupt and long lasting. Sometimes, issues and feelings remain long after the cancer has gone. The challenge is how best to help the woman to cope with the knowledge of her disease and its implications for herself and her family. Support may be required for an extended period of time, in a variety of forms and from a number of different people. This should not be seen as a task that is the sole responsibility of one individual, but will inevitably involve 'the team'. This is best managed by a multidisciplinary team approach, within a designated gynaecological oncology centre, where all members of the specialist support team are available (Improving Outcomes Guidance 1999) and with strong

links to both hospital and community palliative care services.

The carers

The needs of the carers will also be addressed. In order to deal effectively and sensitively with the emotional and practical challenges with which they are confronted through caring for these women, healthcare professionals must understand their own feelings and develop insight into their reactions and coping mechanisms. They themselves may need to explore strategies in order to improve their ability to cope more effectively with the emotional onslaught to which they too are exposed through their own personal experience of care-giving.

Spiritual and Emotional Pain (Box 48.1)

Spiritual well-being has several components: a sense of purpose and meaning in life; a sense of relationship with self, others and a supreme being; and a feeling of hope (Moberg 1982, Miller 1985, Clark et al 1991). Both Clinebell (1966) and Ellison (1983) have identified four categories of basic spiritual needs: meaning; challenge in life; a reason for being; and continuing in the face of adversity. A person's spiritual outlook makes a tremendous difference to the process of both living and dying (Moberg 1982). Spirituality functions as a resource during multiple losses and change (Reed 1987).

Box 48.1 Three steps in the spiritual growth of both doctors and nurses

- Developing a 'greater awareness of the spirit within self' in order to be a better listener for the patient
- Opening the 'self' by being totally present with the patient
- Allowing the patient to share her feelings and emotions without reserve on the health professional's part

Source: From Lane J, The care of the human spirit, *Journal of Professional Nursing* 1987;3: 332–337.

The diagnosis of cancer changes the patient's life forever, causing her to confront her own mortality. The doctor or nurse who cares for these women confronts his or her own mortality an equal number of times (Pace 2000).

If we are able to understand and learn to accept that mental pain is inevitable for both the patient and the carer, we may be freed from feelings of inadequacy and futility, which inhibit important discussion of the woman's hopes and fears.

In order to be effective in these painful situations, doctors and nurses must understand their own feelings and be aware of the natural devices they might use to avoid what may often be a difficult situation and one for which they have received no formal training. Saunders and Baines (1989) use the concept of 'staff pain'. They emphasize the need for staff to grieve the loss of a patient, and the importance of group support for staff and 'debriefing' sessions to allow opportunities to express these feelings in a safe and supportive environment.

Recognition of our own feelings of pain, and acceptance of help from others within the team and/or from a trained external facilitator is the only way to retain the resilience, sense of oneself and the humanity required in order to continue to 'care'.

Times of crisis can usually be turned into opportunities, and the intimacy of such moments between the woman and the doctor or nurse can produce deep feelings, sometimes tears. At times, it is appropriate to sit in silence and just the sense of being there can be recognition enough (Pace 2000). The most important point of all, at the core of every nursing or medical care situation, is the woman's need for someone who is genuine. They need the honest truth, not evasion or empty reassurances. If the healthcare professional has not questioned and analysed his or her own beliefs for the reassurance, doubts and answers they provide, there may be little of value to offer the patient who is forced to confront the ultimate truths and uncertainties of all that comes thereafter.

Care that integrates the spiritual dimensions creates a nurse or doctor who is actually involved in a human relationship. Qualities that demonstrate the ability to provide better spiritual care include a supportive approach to the patient; what has been termed a 'sense of benevolence' to the patient; awareness of the patient, self and the impact of family and significant others; empathy; and non-judgemental understanding (Dickenson 1975).

It takes more than just education for a nurse or doctor to feel comfortable with spiritual issues. Introspection and an awareness of their own personal spiritual journey are

Box 48.2 The changes in sexuality and their effects

- Reduced physical contact
- Loss of intimacy
- Loss of sex drive and desire disorders
- Early menopause
- Infertility
- Reduced human warmth

required to integrate the spiritual domain into patient care (Pace 2000).

It is emphasized that healthcare professionals need to take care of their own spiritual needs. Failure to do so will lead to emotional exhaustion (Lane 1987).

Quality of Life

What is quality of life?

Quality of life was broadly defined as early as 1947, when the World Health Organization described it as 'a state of complete physical, mental and social well-being, and not merely absence of disease and infirmity' (King et al 1997).

Quality of life is a complex phenomenon that affects an individual's personality and lifestyle. It is developed over time with physical, psychological, sociocultural, sexual and spiritual effects (Woods 1975). It is affected by change in appearance, mental states, personal and social factors and, in the case of cancer, the effects of disease process and treatments. It is tied closely to the concept of body image, self-esteem and self-concept, and is affected by attitudes, beliefs and behaviours (Penson et al 2000).

Poor body image can result in the patient feeling worthless as a person; physically unattractive or even repulsive; and unable to feel valued, loved or able to express themselves sexually (Box 48.2) (Dudas 1992). For some women, quality of life means feeling alive. It is personal and individual, and what is considered normal or acceptable to one person or couple may be unacceptable to another.

Effects of gynaecological cancer

The patient

Both the diagnosis and management of gynaecological cancer can have a major impact on every aspect of a woman's quality of life (Donovan et al 1989). It can be an overwhelming experience for a woman and her family. Then, before the woman has had time to work through her feelings of shock and grief relating to the diagnosis, she must begin treatment. There is no doubt that a diagnosis of gynaecological cancer can potentially compromise the key elements described for quality of life: body image, sexual health and relationships (Auchinloss 1989, Colyer 1996). Women of childbearing age experience sadness and anger at the loss of fertility, and women of all ages may view the loss of female organs as a loss of femininity (Steginga and Dunn 1997).

The short- and long-term side-effects of treatment may also affect a woman's self-worth, self-esteem and confidence, and have potential or actual psychosocial and psychosexual

Box 48.3 Physical effects of gynaecological cancer and its treatment

- Pain
- Fatigue and lethargy
- Weight loss and anorexia
- Weight gain (steroids, ascites, lymphoedema)
- Skin irritation
- Odour, fistula, stomas
- Discharge, bleeding
- Vaginal change (stenosis, scarring, dryness)
- Abdominal distension (bowel obstruction, ascites)

implications (Box 48.3) (Anderson 1985, Sacco Ezzell 1999). For example, a premature menopause, hair loss, lymphoedema, a stoma or a surgical scar may impact further on the reaction to the actual cancer (Anderson 1993).

However, it is also important to remember that body image may be altered and affect sexual health and quality of life without any change in appearance, function or control (Price 1990). Being told the diagnosis of cancer may alter body image, as this new knowledge of change may affect the woman's perception of herself and her health. This perception of change can lead to a distortion of body image; the woman may sense that something in herself or in her way of relating to others has changed, even before cancer or treatment have any physical effect. Smithman (1981) points out: 'Some changes in function can be purely psychological, and yet the potential for disturbed self-concept is great'. It is therefore widely accepted that body image, sexual health and overall quality of life are affected by physical factors, physical sensations, and emotional and social reactions.

The partner

It is also important to assess the partner's understanding and needs, as the effect of the cancer is on the relationship as a result of change to either individual. A needs assessment among cancer patients and their partners showed that 63% of the participants would have liked to receive more information about sexual functioning after treatment, and that 64% would participate in a specific counselling programme on the quality-of-life changes if this was offered (Bullard et al 1980).

Model (1990) examined reactions to body image change following surgery in some depth, and linked these to concepts of grief and loss. This is useful as it considers how nurses support both patients and their partners psychologically. Model suggests that we are far from doing this successfully, and that it is important to create an atmosphere in which patients and their partners feel accepted and understood if they experience anxiety, anger or grief, and to provide a medium through which they can express, share and clarify their feelings. Model recommends that the whole healthcare team should work together to do this, which does indeed seem vital, given that many patients and their partners express feelings of isolation following discharge from treatment and for some time thereafter (Colyer 1996).

A high proportion of women are anxious (31%) and depressed (41%) after surgery for gynaecological cancer

(Corney et al 1992). The majority have chronic sexual problems and a high proportion would like further information on after-effects: physical, sexual and emotional. Fifty per cent of young women would have liked their partners to be involved, and 25% of the 40 partners who were involved would have preferred further information.

Ten years on from the publication of these studies, there remains a lack of consistency within both nursing and the medical professions in the ongoing assessment process used to identify change and impact on quality of life for both women and their partners.

What we must try to achieve

The specialist multidisciplinary gynaecological oncology support team has an important role in patient education and management of side-effects, aimed at maintaining or improving quality of life.

Faced with multiple adjustment demands relating to the cancer, the treatments, survivorship issues or palliation of disease and its symptoms, it is important that the couple are encouraged to prioritize what is important to them and have ownership over agreed interventions. It is essential that this assessment not only covers the cancer diagnosis and treatment, but takes into account what life was like for the woman and her partner/family before the cancer (Box 48.4).

It is important that we view the woman as much more than a 'cancer diagnosis' and consider her uniqueness by asking ourselves 'Who is this woman we are trying to help?'. In this way, we can establish how actual or potential change may impact on her current measures for her quality of life. Roles, identity and relationships such as being a wife/partner, lover, mother, daughter, sister, employee or employer, friend and carer may be challenged, threatened and even altered either temporarily or permanently. Issues such as housing, transport, finances, insurance and ongoing responsibilities for paying the bills and child care, along with the challenge of a cancer diagnosis and treatment, may affect her ability to cope. Her usual resources and coping mechanisms and strategies may be challenged to the limit and all this will impact on her quality of life.

Assessing the needs

The effects of both the cancer and treatments have the potential to be both abrupt and long lasting, even when the goal is cure. The impact of altered body image resulting from treatments and/or surgical procedures for chronic illness extends beyond the immediate patient (Wilson and Williams 1988). Therefore, the need for individualized assessment on how this will impact on quality of life, both before and following cancer treatment, is fundamental (Box 48.5). Assessment must be as specific as possible (Box 48.6) and address the woman's concerns by self-assessment techniques.

The changing focus of need

Typically, the focus both before and following cancer treatment is on physical need. However, issues such as being unable to continue to work and the consequent reduced income or transport issues due to reduced mobility

Box 48.4 Aspects of quality of life that may change

- Altered body image
- Low self-confidence
- Low self-esteem
- Unable to deal with losses, i.e. fertility/premature menopause
- Loss of self-concept
- Loss of self-perception
- Loss of femininity
- Loss of control

Emotional impact (grieving scenario)

- Anxiety
- Fear
- Powerlessness
- Anger
- Depression
- Guilt
- Feelings of isolation

Social impact

- Feeling of isolation from:
 - partner/children
 - family
 - friends
 - work colleagues
- Changes in roles/relationships with:
 - partner
 - family/mother
 - work
 - sociocultural
- Impact on resources/finances
 - Unable to work—reduces income
 - Unable to afford to socialize
 - Transport (reduced mobility/isolation)
 - Unable to afford new clothes/extra laundry bills
 - Equipment issues/extra bedding

preventing use of public transport may be paramount, and need to be given priority for the woman and her family. In the initial stages of diagnosis and treatment for a gynaecological cancer, quality-of-life issues may not seem so important and the focus of concern may be on the tremendous physiological demands that occur as a result of coping with the disease process and treatments. However, as the illness trajectory lengthens, previously held notions may change as a woman adjusts to a new identity as a person with cancer.

Quality-of-life assessment and issues relating to the impact of actual or potential change require reassessment during treatment, at follow-up and as part of the long-term rehabilitation process. In women where the cancer progresses or recurs, the goals may change from cure to prolongation of life with the best possible quality for the woman and her family. Criteria for futility must be established to guide the transition from active to palliative management.

Rehabilitation and palliation both begin at diagnosis and continue throughout treatment and follow-up. They address the specific desires of each person and it is recommended

Box 48.5 The assessment process

- Listening to how patients talk about their body, in positive or negative terms
- Observation of how patients behave towards damaged body parts
- Listening to relatives'/visitors' reports about the woman and her methods of coping — is this typical coping behaviour?
- Observing for social withdrawal
- Identify social network/support
- Listening to patients' verbal accounts about how they anticipate life will be beyond the stay in hospital, e.g. how they anticipate others may react to their appearance or body function

Box 48.6 Evaluating adaptation to the cancer and treatment effects

- Has resumed former lifestyle
- Can verbalize concerns over changes in body image
- Demonstrates healthy coping abilities
- Can touch and look at body and accept change due to any scars, stomas or body shape
- Can incorporate necessary change to allow enjoyable activity
- Has incorporated altered body image as part of 'self'
- Shows evidence of high self-esteem
- Is willing to resume sexual relations/intimacy
- Can discuss and consider reconstruction of lifestyle

that they incorporate the contribution of every member of the multidisciplinary healthcare team.

The challenge facing all healthcare professionals is to achieve improvement in the quality of the patient's life by reducing dysfunction and disruption, and providing support with physical, psychological, social and spiritual aspects. In order to achieve this, it is important to identify information needs and individual coping strategies, explore issues identified as important to the patients themselves, and set realistic and achievable goals.

Whilst families are often the primary source of ongoing support to female cancer patients, women also derive considerable support from other patients and from healthcare professionals. The medical team should aim to develop psychological and psychosexual skills to cope with this important area of care. Further research is also needed into how support groups may best meet patients' needs (Veronesi et al 1999) and those of the care providers.

What we must learn

The following are essential in empowering both nurses and doctors to undertake their role: a comprehensive understanding of the aetiology of the gynaecological cancer and the effects of both the disease and treatment; knowledge of the ways of minimizing adverse problems; and assisting the woman and her partner in managing their needs.

Healthcare professionals must develop an appreciation of the wider issues and literature surrounding sexual health, altered body image, gender identity, role identity, cultural

issues, religious beliefs, and how all the factors can influence self-esteem and body image and impact on quality of life in either a positive or negative way (Masters et al 1995).

Concern is often expressed in clinical practice that health-care professionals lack the time and skills to deal with psychological and quality-of-life issues, although the literature suggests that giving patients the opportunity to express such concerns can be preventive of problems as well as therapeutic (Auchinloss 1989).

Despite its importance, quality of life is rarely a reported outcome in randomized clinical trials in cancer patients. Gynaecological oncology nurses, clinicians, educators and researchers must continue to work collaboratively to enhance the knowledge base regarding quality-of-life issues and to improve care provided to women with gynaecological cancer (King et al 1997). The impact of a gynaecological cancer on a woman's quality of life is an important outcome parameter that may be measured as survival without significant morbidity (Anderson and Lutgendorf 1997).

Psychosocial Issues and Returning to Normality

The woman may have undertaken several different roles and responsibilities prior to the cancer diagnosis and treatments. She may have been the central supporting figure in a household of some complexity, and may have provided the economic support, as well as the responsibilities of a mother, a partner, a lover and a homemaker. The very act of returning to any or all of these roles is often a significant milestone in recovery.

Apart from the obvious anxieties about her prognosis and family relationships, financial worries and change in role can be an immense source of stress for the patient and partner. The potential for this needs to be assessed prior to treatment and at subsequent follow-up.

Often practical help can be offered, such as a letter to the employer or facilitating the intervention of social services, and giving information on benefit entitlements and grants (e.g. Macmillan) where patients are unaware of possible financial assistance, and help in dealing with transport problems.

For patients living with severe ongoing disability due to the cancer or its treatment, or those with progressive disease where the aim is no longer cure but palliation, additional grants such as disability living allowance, attendance allowance and 'special rules' or palliative care funding may be applied for. The benefits helpline should be contacted to clarify eligibility.

The issues that must be addressed (Box 48.7) may be ongoing, and follow-up appointments provide an opportunity to assess how the woman and her family are readjusting to life following cancer.

Sexuality and Psychosexual Issues Relating to Gynaecological Cancer

In 1986, the World Health Organization stated that key elements of sexual health were:

Box 48.7 Issues that must be resolved

- Childcare issues
- Relationship dynamics
- Work-related responsibilities
- Housing needs
- Transport, travel, parking and fares
- Finances and adequate social resources
- Loss of fertility and premature menopause issues

- a capacity to enjoy and control sexual and reproductive behaviour in accordance with a social and personal ethic;
- freedom from fear, shame, guilt, false beliefs and other psychological factors inhibiting sexual response and impairing sexual relationships; and
- freedom from organic disorders, diseases and deficiencies that interfere with sexual and reproductive function

A gynaecological cancer diagnosis and treatment may threaten or actually change the key elements described for sexual health, and are associated with considerable sexual dysfunction (IOG 1999).

The background

A woman's physical genital development, her attitudes and security about being a woman, and her view of herself in relation to others, especially in intimate relationships, are all part of her uniqueness. Sexual functioning and concerns vary throughout one's lifespan and cannot be assumed for any age group or extent of disease. A woman's genital region may be perceived as psychologically very special, being both exquisitely sensitive and primal in sexual arousal. A malignancy in this area may be especially disturbing and significantly different in its emotional effects from cancer in other parts of the body. Reactions may vary according to feelings of the individual woman about her genitalia prior to developing a gynaecological cancer. However, there is no doubt that cancer of the vulva, which necessitates very evident vulval mutilation as a consequence of surgical treatment, can produce severe problems with psychosexual function (IOG 1999).

The quality of a woman's life needs to be considered and assessed in relation to what it was before she became ill. An unsatisfactory relationship prior to a cancer diagnosis may be improved by a couple having to cope and coming closer together. Alternatively, poor relationships may continue to be devoid of intimacy and affection. How the effects of the cancer and its treatment impact on either of these scenarios needs ongoing assessment.

Effects of gynaecological cancer

A study by Cull et al (1993) included 83 women with early-stage cervical cancer, half of whom had received surgery and half of whom had received radiotherapy. They were studied by standard self-report questionnaires and semi-structured interview. Over half reported deterioration in

sexual function, and the irradiated women suffered more with loss of sexual pleasure. Many women felt that their psychological needs were not being met adequately.

A similar UK study included 105 women who had undergone radical pelvic surgery, of whom 65% had been treated for primary cervical cancer (Corney et al 1993). The mean time since treatment was 2 years. Of 73 women in whom the vagina had been preserved and who were in a sexual relationship, 16% never resumed intercourse. Two-thirds were experiencing sexual difficulties and around half reported a deterioration in their sexual relationship. However, this study highlights the need to never 'assume' as, interestingly, around one-third of these couples felt that their marital relationship had actually improved.

The need to provide information

The inadequate information about the effects of disease and its therapeutic interventions on people's sexual function and alterations in their quality of life is also reflected in the scarce amount of empirical research available on these issues. All oncology professionals should be aware of the importance of recognizing and addressing issues of sexual function as an integral aspect of quality of life for people with cancer and their partners (Gallo-Silver 2000), and both nurses and doctors need to develop skills in talking to patients and partners about sexual concerns and in taking a sexual history (Smith 1989, Green 1999).

Sexual function is an essential and fundamental area of the assessment process and should be discussed in a continuous fashion, rather than a haphazard or one-off fashion. A woman diagnosed with a gynaecological cancer and needing to undergo any form of treatment may have concerns relating to potential change in her sexuality or sexual function. However, she may be too embarrassed to ask and may worry or fear that it may be perceived as inappropriate to ask or discuss.

In a society that has moved rapidly towards an awareness of sexuality of all ages, these patients will demand, not without justification, that medical science passes both appreciation and expertise concerning this dimension of their disease.

They will require and expect therapeutic interventions which will assist them in becoming psychosexually as well as physically rehabilitated (Derogatis 1980).

The goal of intervention

The goal of sexual rehabilitation is to restore the patient's ability to engage in intimate interpersonal relationships, and incorporates the restoration of self-esteem and bodily function or adaption to change (Bancroft 1989). When appropriate and desired, sexual rehabilitation includes restoring physical ability to engage in sexual activity. Sexuality is an important aspect of quality of life and has a tremendous impact on an individual, their partner and families (Rutter 2000).

Listening and asking

Loss of sex drive may arise from an altered body image or there may be unresolved feelings such as guilt or fear of an

association between sexual intercourse and cancer. Full assessment, discussion and information about the facts, in order to remove any misconceptions, are essential. The effect of the diagnosis on the partner is often overlooked, but it cannot be emphasized too strongly that preparation for the couple is the key to preventing avoidance or silence. The partner may fear that he could hurt or harm the woman, and other misconceptions that he can 'catch' cancer himself through being intimate may cause a barrier between them. Simple explanations and reassurance both before and following treatment, involving both partners if possible, can prevent problems arising or minimize problems by recognizing the important issues early.

Sexual functioning should be enquired into at the early follow-up visits and assessed continually, so that if any changes or difficulties occur, they can be recognized, support can be offered and appropriate interventions or specialist psychosexual referrals can be made as appropriate.

Sexuality may be expressed in a multitude of ways so it is imperative that healthcare professionals do not make assumptions about sexual behaviour, and understand that information assists women in regaining a sense of control over their behaviour and destiny (Burke 1996). This applies just as much to the late stages of the disease as to the early phases of the journey.

When physical love and intimacy have been important and are suddenly withdrawn, their loss is felt. Even when they have not been important, their need may now be recognized. We cannot assume. However, loving touch in the palliative stage of the disease process may be avoided for fear that it may lead to more sexual intimacy. This may be overcome if both partners are able to discuss their anxieties, either with each other or facilitated by a healthcare professional.

The woman may not touch her partner or avoid closeness for fear that it might lead to physical sex. The man may be just as fearful that coitus would damage or hurt his partner, and consequently keeps his distance. Both should be reassured that sexual intercourse is 'acceptable' at any stage of the disease process if there is sexual desire and drive on both sides and if it is physically possible. However, when coitus is not physically possible, methods of mutual masturbation can be explored, and sexual expression using sensate focus techniques can be explained (see below).

Communicating a willingness to assist women to ways to express their sexuality in spite of the cancer and consequences of treatment can be a challenge (MacElveen-Hoehn and McCorkle 1985). Basic counselling skills such as listening, a non-judgemental approach, and an open and accepting attitude with clear boundaries help to legitimize concerns as normal and valid (Lamb 1985, Laurent 1994).

Intervention

Both cognitive and behavioural sexual rehabilitation interventions have been suggested to assist women and their partners to adjust to the physical, psychological and psychosexual changes due to cancer and their impact on the relationship (Gallo-Silver 2000). The interventions described aim to increasing understanding and gradual adjustment, allowing the woman and her partner to have 'ownership' over the interventions chosen and to regain control.

Understanding and familiarity of appropriate use of the following interventions can prepare healthcare professionals to assist patients and their partners with sexual needs and concerns:

- educating patients about the phases of sexual functioning and the impact of treatment;
- giving permission to explore their ability to respond to sexual stimulation by using self-pleasuring exercises; and
- teaching sensate focus exercises that structure non-coital foreplay and suggesting changes in coital positions to increase both access and comfort.

The P-LI-SS-IT model (Box 48.8) (Royal College of Nursing 2000) is a framework for assessment of sexual need and can be useful as part of the multidisciplinary team approach to assessment of sexuality in women with cancer.

Box 48.8 Outline of P-LI-SS-IT model

Level 1: Permission (P)

The challenge for all healthcare professionals at level 1 is to create a comfortable environment that gives patients permission to discuss concerns and problems related to their sexuality and sexual health by:

- ensuring the physical environment is comfortable and private;
- communicating to the patient using acceptable counselling skills such as openness, reflection and paraphrasing;
- using cue questions to give the patient the opportunity to raise any sexuality and sexual health concerns;
- giving reassurance, where required, that the patient's current sexual practices are appropriate and healthy or that experimentation is appropriate;
- having a range of information available that is educational and non-personal;
- knowing where to get further information from and routes of referral for the patient;
- acknowledging the needs of sexual partners; and
- acknowledging the sexuality and sexual health needs of patients in relation to their cultural background.

Level 2: Limited information (LI)

This is where healthcare professionals provide non-expert or limited information relating to sexuality and sexual health. For example, a woman receiving pelvic radiotherapy will need to know about vaginal dryness and possible implications for her future fertility.

Level 3: Specific suggestions (SS)

To provide specific suggestions to help patients with sexuality and sexual health needs, healthcare professionals complete training at specialist practitioner level.

Level 4: Intensive therapy (IT)

The most advanced level of addressing sexuality and sexual health care involves complex interpersonal and psychological issues and is used with patients who have specific sexual problems such as dyspareunia or vaginismus. Relationship counselling falls into this category. Further training is needed in psychosexual medicine and relationship therapy to undertake this stage.

Source: Royal College of Nursing 2000 P-LI-SS-IT model. In: *Sexuality and Sexual Health in Nursing Practice*. RCN, London.

All patients need permission and limited information, frequently dispelling myths and eliminating ignorance about the disease and treatment effects on their sexuality. This is often enough to enable patients to resume sexual expression and intimacy. Specific suggestions can help patients whose radical surgery or radiotherapy treatment has resulted in physiological or anatomical alterations, such as a stoma formation or vaginal stenosis, or when the mechanisms of sexual response have been affected.

Despite careful assessment and interventions, problems may still arise and expectations may not be met. The need for the skills and expertise to provide in-depth assessment of need and intensive structured therapy in the form of marital or sexual counselling is recognized in the P-LI-SS-IT model (Bancroft 1989, Penson et al 2000). Doctors and nurses need to be secure in the knowledge that it is appropriate to refer to a sexual therapist as the need is identified with the patient or couple.

Behavioural therapy

Direct behavioural approaches for treating sexual dysfunction due to performance anxiety are advocated (Masters and Johnson 1970). Sensate focus may be useful as it is aimed at regaining intimacy within the relationship through mutual touching and physical sexual sensation and stimulation of each other's body parts, while not necessarily needing to involve the genitals or the act of intercourse. It is essentially about being able to communicate and relax with their partner, and developing a sense of trust and closeness which may have been lost (Leiblum and Rosen 1989). The sensate focus method restructures and reorients how couples may ordinarily approach sexual interactions, allowing them to move away from old familiar habits and reinvent the physical side of their relationship. It is about touching and being touched. However, at the heart of the programme is an initial ban on sexual intercourse, particularly genital contact and penetration, until performance anxiety and fear of failure have subsided and trust within the relationship has been re-established.

Finally

For a woman to be sexually complete, she must feel secure and this is a fundamental need for a woman facing the future, especially when she is terminally ill. Respect, trust and love are needed in order to establish security. Fear, distrust and anger need to be dispelled. Respect includes self-respect and this may have been absent even before the occurrence of cancer. Altered body image may exacerbate already fragile and vulnerable emotions around oneself. To acknowledge the hurt and pain of emaciation, hair loss, discharge, bleeding, abdominal distension, colostomy or urostomy is difficult, and it can help to share this difficulty by not avoiding the important issues for the woman. Love of the person rather than the body must be constantly reinforced. There is an opportunity to engender new self-respect and trust, in discussing openly and honestly the issues that may be painful but most important to the woman at that time.

Breaking 'Bad News'

'Bad news' can be defined as any information that dramatically alters a patient's view of her future for the worse (Kay 1996). The way in which bad news is delivered affects both the patient's and the family's ability to cope, and should therefore be done in a sensitive and, where possible, planned and supportive way.

It is in the nature of gynaecological malignancies that the possibility of cancer is uppermost in the patient's mind even before the investigations that confirm her worst fear. Most studies in which patients with cancer have been asked how much information they want report that over 90% want all the information available, good or bad.

Bad news may be broken in the following circumstances:

- at the point of diagnosis;
- at the point of recurrence; and
- when entering the terminal phase of illness.

The manner in which this responsibility is undertaken determines the subsequent relationship between the patient and the healthcare professional. Trust and respect established at this time will ease future care and the relationship between them.

Breaking bad news well is important for the following reasons:

- to maintain trust which enables the relationship between the patient and healthcare professional to be based on openness and honesty;
- truthfulness about the disease allows open communication with the patient and fosters discussion about the disease process and its management;
- uncertainty may be reduced;
- to prevent the demoralization caused by unrealistic hope;
- to allow appropriate adjustment of the patient and her family, empowering them to make informed decisions about their future care;
- to prevent collusion with family members which destroys family communication and prevents mutual support; and
- information/bad news given to the patient and her family must be communicated to the patient's primary, secondary or tertiary care team to allow open and sensitive communication between care settings.

Standards of care suggested for breaking bad news

The specialist in charge must ensure that members of the multidisciplinary team have appropriate training and skills in breaking bad news. The patient's autonomy must be respected when making management plans. In this way, the patient will be given the option of involving a family member or carer to support her at the time of breaking of bad news. The doctor or specialist should plan, whenever possible, how this will be done, the setting and with a specialist nurse or appropriate member of the team present. It is the responsibility of the specialist team to ensure swift communication and liaison between the hospital-

based team and the primary care services when bad news is broken.

The actual process of breaking bad news

Preparation

- Ensure all information is available (e.g. diagnostic information, knowledge of all the facts).
- Have a defined treatment plan/options available prior to the interview.
- Give the woman notice of the interview to enable her to invite a family member or friend.
- Invite a specialist nurse/support nurse to be with you whilst breaking bad news.
- Ensure that privacy is maintained with no interruptions; no telephones, beeps or pagers; and an 'engaged' or 'do not disturb' sign on the door.
- Set time aside, indicate how long and indicate that arrangements can be made to meet again if needed.
- Book an interpreter if needed. Do not use a family member to break bad news.

The doctor's role in the breaking of bad news

- Give time, do not appear to hurry. Sit down facing the patient and her family (if present).
- Make any necessary introductions, including the family members and specialist/support nurse.
- Make eye contact.
- Find out the patient's perception of the situation.
- Ask if the patient wants more information (e.g. 'I have the results of your tests, would you like me to explain them to you now?').
- Avoid the use of medical jargon, use the patient's language. Be honest and clear.
- Give a warning shot (e.g. 'I'm afraid it looks rather serious'), followed by a simple, sensitive explanation, avoiding too much detail at this stage, unless the patient asks, as she will not remember everything that is said because of the shock process.
- Be optimistic and maintain realistic hope (e.g. 'There are things we can do to help you').
- Use the word 'cancer' and avoid the use of euphemisms.
- Stop at this point. Allow the patient time for expressions of feelings or stunned silence.
- At this point, check the patient's understanding of her situation now.
- Continue at the patient's pace with information-giving.
- Expect expression of feelings and sometimes angry questions.
- Be prepared to repeat yourself as details will not be remembered.
- Discuss treatment plan, time scales and other written information.
- Ensure the interview is closed sensitively and inform the woman when she will see you next or how to contact you if necessary.
- Offer to meet other members of family separately.
- Bad news will always be bad and will always be remembered, as will empathy and simple, clear, well-planned, sensitive and honest explanation.

The nurse's role in the breaking of bad news

- Be prepared to co-ordinate the process.
- Ensure a quiet room is available or screen off the bedside; no interruptions, bleeps, pagers or telephones.
- Make sure the patient and family are comfortable and all seated.
- Ensure the doctor is able to sit down comfortably to enable him/her to maintain eye contact throughout.
- The nurse's role is to support the patient, the family and the doctor.
- Ensure the patient's dignity is maintained at all times (e.g. dressed/covered before the consultation begins).
- If the woman is an outpatient, ensure that if she is alone, there are transport arrangements home and someone to collect her if in shock.
- It is necessary to ask the patient's permission to contact her general practitioner (GP) and any community support service (e.g. Macmillan).
- Stay with the patient and family following the interview. Allow time for them to compose themselves and the opportunity to ask questions.
- Offer relevant written information and contact numbers for the patient and family to access further information or advice (e.g. Macmillan nurse/support groups).

After the consultation

- The nurse should be available to the patient and family for as long as necessary.
- Ensure that the next appointment is made for further investigations, treatment, symptom review and follow-up.
- Offer nurse-led follow-up in the form of personal or telephone contact.
- Ensure that the GP is informed, and local community support as appropriate (e.g. Macmillan team/district nurses), as soon as possible by either telephone or fax regarding the bad news given, treatment plan and how the patient and family received the news. Indicate the name and contact number of the support/specialist nurse involved.

Dealing with collusion and the conspiracy of silence

Family distress at anticipated bad news can lead to collusion which, in turn, leads to poor communication between the family, patient and healthcare team. Some patients may not wish to have detailed information, and elect to permit their information to be discussed with the family or a carer.

To prevent collusion occurring, the following should be addressed.

- Deal with the patient's main concerns first.
- Ask the patient's permission to see the family/carers.
- Talk to the family/carers. Gain their trust to enable them to give 'permission' to talk openly and honestly.
 - Acknowledge that they know the patient best.
 - Check the family's understanding of the illness.
 - Check why the family do not want information given to the patient.

- Indicate potential difficulties the family may experience if the patient is not told the information if she asks.
- Ask permission to talk to the patient alone to elicit what she would like to know.
- Talk with the patient.
- Talk with the patient and family together.
- Document the outcome of discussions.

Relatives often ask that the patient should not be told the diagnosis. This wish can sometimes be very strongly stated, and may be driven by a strong desire to protect the patient. It is important to discover whether this is because their own fears are too great to face.

If the opportunity is given to discuss the woman's illness, with care and support for the whole family to cope, a very positive outcome can result. The alternative is that the strain of pretence will undermine patient and family alike, with both sides usually being unaware of the reality of the situation, even if this is not admitted (Twycross and Lack 1983).

Modern cancer treatment, often involving radical complex surgery, chemotherapy and radiotherapy, can hardly be carried out without the patient realizing she has cancer. Even if the medical and nursing staff collude with relatives to conceal the diagnosis, day-to-day discussion and comparison of treatments with other patients will usually result in her guessing the truth.

If an open, honest approach is not adopted from the onset of the relationship with the healthcare team, it imposes an almost intolerable burden on the person who is fully informed. There is a tragic irony in the situation where the nearest relative has been told the diagnosis but tries to preserve a façade, while the patient who has guessed the truth attempts to maintain a brave face for the benefit of her relatives. They are each left to face alone the prospect of uncertainty around the diagnosis of cancer, and the relatives are separated from the woman by this conspiracy of silence. It is far more constructive to be able to discuss their fears with each other, and to provide the close emotional support that they both need and deserve.

Giving the patient opportunities to ask and replying honestly

Simple questions such as 'Have I made myself clear?' or 'Is there anything I have not yet explained that you wish to know?' will give the woman a cue to discuss concerns. It is important to be aware of body language, both our own and the patient's, as this can speak volumes. Try to sit at the same level as the patient and maintain eye contact. Avoid any obstacles to open communication such as lack of privacy, constant interruptions, telephone calls or even interposing large desks. If an authoritarian posture is avoided, patients will be more likely to express their fears and feelings around what is always going to be a difficult subject.

Letting the news sink in

Patients' frequent dissatisfaction with the explanations given to them may not be due solely to a failure of communication or lack of time. They may not retain the information or may even suppress it when the content of the conversation is emotionally distressing and too painful to absorb.

Women often report that they 'shut off' and 'could no longer bear to listen'. Hogbin and Fallowfield (1989) have suggested that tape recording 'bad news' consultations and giving the tape to the patient to take away with them may help them to understand the problem, overcome failures of recall, and explain the diagnosis and any treatment plan to their relatives.

However, this approach may not suit every patient and may create further obstacles to communication by preventing the interview from achieving the degree of privacy and intimacy which is necessary for two-way open interaction.

Another suggestion is to write down the facts from the information given verbally following the consultation in which bad news is broken, and allow the patient an opportunity to absorb the information at her own pace over time and once the shock process has started to shift. Once the reality of her new situation has sunk in, the need for more factual information and exploration of the options in order to take back some control often takes over from initial fear, shock and stunned silence (IOG 1999). Written information following the breaking of bad news can then be extremely useful in helping the patient and family to formulate their questions prior to their next consultation with the specialist team.

Many areas also have local cancer support groups and there are national cancer helplines which may also be useful in helping patients to come to terms with the 'bad news' given (see Sources of support below).

Being realistic

It is important to be realistic at all times and to avoid giving false reassurance. At the same time, it is important not to deny the patient all hope. Encouraging a positive but realistic attitude will help. The importance of this stage cannot be emphasized too strongly. If the multidisciplinary care team forms an open and honest relationship when there is hope for cure, this will be far easier for the woman to accept if disease recurs or her condition does not respond to treatment and she enters the palliative stage of her journey. Some women will choose to cope with the news by denial. They should not be assaulted with the truth but allowed to come to terms with the situation in their own time. No response is needed other than gentle reiteration of the truth, relating the known facts when requested. Denial may, in part, be responsible for a woman's apparent lack of understanding after the initial interview. In this case, it should be carefully noted for use in further meetings, in order to manage her care in a professional, sensitive and individualized manner.

Talking to Children about Cancer

What makes cancer especially difficult are the many unknowns. Living with uncertainty is part of having cancer. There are some questions that cannot be answered. Helping the patient and her partner to accept that fact and to find out all they can to make the unknown more familiar to them is the first step in allowing them to be able to talk to their children and help them to accept the fact too.

Children need to be given information about their mother's condition, to a degree dependent on their maturity, in order to understand and cope with what is happening. Honesty is very important when communicating with children. The best person to give children information is the parent or another close family member. If they feel unable to do this, they can enlist the help of a professional; for example, a member of the multidisciplinary specialist cancer care team, a counsellor or social worker. However, it is important that the parent is present when the child is told bad news so that they know exactly what has been said and can comfort them with their immediate reaction to it.

Everyone who has a relationship with the patient will be affected by the cancer diagnosis, even if they do not show their feelings. If their mother is frequently absent or not well enough to care for and play with them as she did prior to her illness, children may feel inexplicably rejected. Without reassurance, a child may feel responsible for his or her mother's illness or subsequent death.

A child's understanding of illness and death, although not the same as an adult's, is often underestimated. Children can often accept the inevitable more easily than their elders. Sometimes all that is needed is time to adjust and the maintenance of some routine and stability. However, there are things that parents can say or do to help their children to cope with change and uncertainty.

Children need to be given information in a way they can understand. It is important that jargon and excessive medical details are avoided. Tell children what has happened, explain what will happen next and be prepared to repeat the information and to ask children questions to check whether they have understood what they have been told. The use of drawings or story books can help younger children to understand. Children need accurate information about cancer, not fears and assumptions gleaned from other sources.

It is important to ask children whether they have any questions and to let them know it is all right to ask anything they want. Children often take a long time to process information and may need to come back much later and ask more. As well as telling them about changes, it is important for them to know what will stay the same. Reassurance that they will always be looked after and loved in spite of the illness will help maintain feelings of security. However, false promises must be avoided, as cancer involves great uncertainty.

It is important to listen to children, as they will let us know what they can cope with. Honesty about what adults do not know is as important as sharing what we do know if children are to continue to trust. A child has a right to know anything that affects the family, as cancer does. Not telling them may feel like a breach of trust and children usually know when something is wrong. If parents try to protect them by saying nothing, they may actually develop fears which are worse than the real situation. Children can be left feeling isolated if they are not told the truth. Attempts to protect them may enhance their anxiety. Children have an amazing ability and capacity to deal with truth. Even sad truths can relieve the anxiety of too much uncertainty. Through sharing their feelings and being prepared to acknowledge and express sadness, the parents can offer support for their children.

Coping with cancer in the family can be an opportunity for children to learn about the body, cancer, treatment and

healing. They can also learn about feelings and the strength of the human spirit in difficult times. Telling children means that they can share significant emotions with their parents and siblings. Children need to be given permission to feel sad, angry or scared. Children are very resilient. They can cope with difficult information if they are supported with it, left with a feeling of hope and assurance that they will still be loved and cared for.

It is important to talk to children individually as children's understanding and their concerns differ with age.

Children aged 3–7 years

Young children need very simple explanations of the cancer. The use of drawings will help to explain it to them, and will also help parents to understand their worries and feelings. At this age, children are very wrapped up in their own world and will be concerned about whether their needs will be met in this frightening situation. This anxiety may be expressed through regressive behaviour (showing the behaviour of a younger child) such as tantrums and bedwetting.

It is important that parents maintain their usual routine to provide reassurance, enlisting the help of other relatives and the child's school to do this. Discipline needs to be consistent, rewarding good behaviour and providing extra affection. Difficult behaviour should settle down in time as it is a normal reaction to stress and change.

Major fears for children of this age will be change in a parent; this may be frightening, such as hair loss, sickness and separation from the mother if she has to be admitted to hospital. Children will need a lot of reassurance from the mother and their well caregiver in order to cope with this change. Things that may help are simple information, use of calendars to help them understand time scales, reading them books about hospitals, explanations of how equipment works, creating a child-friendly environment in the hospital as much as possible, frequent visits to the ill parent, making cards and tapes for them, and speaking frequently to their mother on the telephone. For younger children especially, it is important to use the correct language and explain things literally as they may not understand what cancer, illness or death means. Using vague explanations about a mother's death, such as 'Mummy has gone to sleep', should be avoided as it may leave a young child confused when their mother does not wake up, or lead to fear of going to sleep themselves and nightmares.

Children aged 7–11 years

At this age, children have a more complex understanding of the situation. They will very often worry greatly about their mother and what will happen in the future. This may lead them to protect her by not asking questions or raising their fears. Keeping communication open and encouraging the children to do the same can be positive. It is important to let the school know so that they have alternative sources of support if they need it. Again, behaviour may be affected; children may become more aggressive or more withdrawn. Schoolwork may be affected. It is important that parents provide a lot of reassurance and support, as well as maintaining firm boundaries with regards to discipline.

Teenagers

Adolescents have a particularly difficult time, as they are already struggling with all kinds of development issues. They are trying to find a new identity and balance between dependence and independence. A mother's illness will challenge this balance and may promote resentment and anger in the child, which ultimately leads to guilt. They may rebel to a greater degree, exhibiting a lot of anger, or alternatively they may mature too quickly and take on a lot of responsibility.

After treatment, it is important that parents continue to keep children informed of what is going on and to balance hope with reality. If the mother's cancer recurs, children will need to know this. There may come a time when the reality is that the mother is not going to recover. This will be an incredibly difficult time for the parents and it may seem even harder to discuss this awful reality with children. Death and dying are not talked about openly in our culture, and it may be difficult for the mother to face the knowledge that she is going to die. It will be difficult for the whole family, including the children; facing it together and allowing them to be part of that process is likely to help them face the future.

It is vital that parents are honest and discuss the reality with children, as it makes it harder for everyone to cope if they are kept in the dark. Like adults, children need to prepare for loss and have the opportunity to say or do important things for their mother.

Children often know much more than we imagine and need to be given permission to talk about it. It is important to use language that they will understand, avoid jargon and use open, honest and direct communication. Most importantly, children need to be listened to. Parents can help their children face life afterwards by preparing them for the future without their mother. This is never going to be an easy process but however long a mother may have to live, time with her children can be precious. The whole family may discover reserves of love and inner strength that will enhance the rest of their life together.

Emotional difficulties linked to cancer are not always easy to talk about and are often difficult to share with those to whom we are closest, especially when children are involved. Trained counsellors in cancer care use their skills to help people talk about their thoughts, feelings and ideas, and may help in the process of untangling some of the difficulties and confusion that living with or dying from cancer can bring.

Recurrence of Disease and Cessation of Active Therapy

For the woman who hopes to be cured, the discovery of the recurrence of cancer is a time of great despair, rage and fear. This is often worse than the time of initial diagnosis and can be devastating. The three causes of anguish and anger described most commonly by patients are: delay in diagnosis; not being told the diagnosis until they were too ill to complete unfinished business; and return of the cancer when they felt they had been assured of cure.

The resentment at having been cheated can be great. For some, it is simply having cancer; for others, the word 'cure'

has probably been 'heard' rather than said, but all feel that false hope has been given. The balance between false hope and no hope is difficult to achieve but is important (Saunders and Baines 1989). Anger may also be accompanied by spiritual pain. If this anger is accepted and understood, the path to acceptance is cleared. If it is not understood, and especially if it is met by a defensive attitude, it may increase as unresolved or unexpressed anger and may lead to depression (Massie and Holland 1989). Permanent, intermittent or transitory denial of the prognosis represents a necessary defence mechanism against a massive assault on the mind and emotions, and should be treated as such; the patient should be allowed to accept her situation at her own pace (Kay 1996). Cessation of active therapy means that the woman may now be facing the terminal stage of her journey. This knowledge is accompanied by new fears: the course of the disease, disfigurement, dependency, loss of self-respect and dignity, dying and the manner of dying.

Open discussion, honesty and acknowledgement of these anxieties with all concerned will help towards emotional security. Stopping treatment need not remove all hope. The nature of hope is to be flexible: hope for cure can be replaced with hope for time, and an opportunity to complete unfinished business or to aim for a particular personal milestone. Loneliness and a feeling of isolation are not only hard to bear in themselves but also heighten other symptoms of advanced disease. The isolation is sometimes imposed by the woman herself when the thought of parting becomes intolerable (Maguire 1993).

It is impossible to overestimate the benefits of an offer of palliative care; Macmillan nursing support, both community and hospital based; cancer counsellors and the specialist gynaecological cancer nurses. Even if little physical help is needed, the psychological support and ongoing relationship with the specialist multidisciplinary support team cannot be introduced too early. Palliative care support begins at the time of diagnosis, when there is uncertainty, and provides a natural link for the woman throughout her cancer journey. It is an important role for her and her family in providing reassurance that she will not be abandoned when there is cessation of active treatment. The focus of care will now be on her symptoms, psychological support and individual needs rather than her tumour. It is vital to watch and listen with care and to respond to what is seen and heard.

Now the patient has to face the more immediate prospect of death, it is possible to deal honestly with her without moving into stark truth (Saunders and Baines 1989). The immediate reaction may be disbelief or denial (Faulkner and Maguire 1994, Kay 1996). She may react with anger, either immediately or at a later stage. Depression is common and these different emotions may occur at any time; daily alterations between one and another are possible. The depression which may follow the woman's realization of the severity of her illness should not be confused with endogenous depression. When an individual is faced with the imminent prospect of death, depression and grief are appropriate, not pathological reactions (Massie and Holland 1989).

Although most patients welcome the truth, it may take some time and much discussion on several occasions for her to face her situation fully. She needs to feel she can survive as a fully integrated person, whatever length of time she has and however the disease process or treatment affects her.

There needs to be room for hope and for denial (Pace 2000). A scientific approach often suggests that we must give patients 'the facts' and help them to 'accept the truth', but denial may be a functional and appropriate coping skill at that particular time (Corless 1992). As the old hospice adage goes, unless something is terribly wrong with where the patient is, that is perhaps where the patient needs to be.

Reactions of partner, family and close friends

The partner, family members and close friends often exhibit similar reactions of grief, anger and denial. However, this is unpredictable, as is each person's individual reaction to a natural process of loss and change.

How each deals with that experience will be different depending on their individual relationship and their usual personal coping mechanisms. Feelings of loneliness and isolation are particularly difficult to endure for both the patient and those close to her, and are not helped by mere physical proximity to each other. They each need time and space to express themselves and what they are really feeling.

Family and friends who do not express their emotions or acknowledge either their own or the patient's pain may simply not know what to do or say, and it may be sufficient to show them that simple, truthful exchange is not damaging. The thought of loss may be unbearable and may be managed by assuming a routine and not facing up to the reality of change for both the woman and those close to her. This can be painful for the patient and cause anger and resentment unless its cause is understood. The partner may also feel isolated, emotionally and physically impotent, fearful of not being adequate and unable to bear the thought of any loss or death.

Close involvement in emotional support and practical care may ease the burden if sufficient confidence and professional help is provided. Trained cancer counsellors, Macmillan nurses and specialist gynaecological cancer nurses offer a service aimed at psychological support for the partner and family from diagnosis and throughout the journey, and either provide or refer on the appropriate bereavement services.

Fear of symptoms in advanced stage of disease

The patient's mental state will profoundly affect her symptomatology (Faulkner and Maguire 1994; Twycross 1997a). Fear of symptoms causes anxiety in the palliative stage, not only for themselves but for the significance they bear. If this is discussed fully with the patient and relatives, the anxiety can be diminished and the future can be faced with confidence that problems will be taken seriously.

The symptom most feared by patients and their families is pain. It was Cicely Saunders who first discussed the concept of 'total pain', which includes psychological, emotional, social and spiritual components as well as physical pain. Mental pain may present as physical pain or contribute to the extent of existing symptoms. Even mild pain should be taken seriously, so that confidence is established that pain can be treated quickly and effectively. When psychological adjustment and acceptance are achieved, the quantity of analgesia required may be reduced markedly.

Saunders and Baines (1989) have stressed the role of symptom control, but also point out that this requires time and close contact with the woman to give her the confidence to impart her deeper feelings, whether they be of anger, depression, guilt or regret. Guilt, anger and grief all need to be expressed, understood and acknowledged as valid, even if answers cannot be offered.

Factors that lower the pain threshold include fear, anger, sadness and boredom. Sympathy, understanding, companionship, diversional activity and elevation of mood raise the pain threshold (Twycross and Lack 1983).

Good communication which allows expression of fears and anxiety, and that conveys understanding and support can be a powerful means of alleviating pain. In some instances, the relief of persistent pain may require no more than providing the honest communication that has previously been denied to the patient (Lichter 1987).

It is a feature of all aspects of modern life that inadequate attention is given to spiritual needs. The effect on both the dying and those caring for them is 'spiritual pain'. Religion is a component of spirituality but is not always the total whole.

Man is not destroyed by suffering, he is destroyed by meaningless suffering (Frankl 1987).

Symptom control

The psychological and emotional aspects of care cannot be adequately assessed and managed if a woman is experiencing uncontrolled physical symptoms. Moreover, the patient's mental state will affect her symptoms profoundly.

The aim of symptom control is to release the woman from physical distress so that she can focus on important issues, such as:

- rehabilitation;
- changes in role;
- emotional adjustment;
- focus on relationships;
- unfinished business;
- meaning of life (Kay 1994).

Treatment goals must be realistic. The aim is to free the woman from the limitations imposed upon her life by the symptoms, as far as possible. This needs to be approached by a specialist multidisciplinary team wherever the woman chooses to be looked after (i.e. home, hospital, hospice or nursing home). Expert nursing care needs to be offered, including gynaecological cancer nurses, palliative care nurses and community Macmillan support and district nurses; counselling; palliative care doctors; rehabilitation services, including physiotherapists, occupational therapists, social workers and complementary therapists; spiritual support; family support; terminal care and bereavement services.

Physical, social, emotional and spiritual needs are often combined and can be complex. They will require time and sensitivity from a team approach in order to manage care.

Principles of symptom control

- Listen to the details.
- Ask about all symptoms.

- Detailed drug history.
- Ask why the symptom is occurring. Look for reversible factors.
- Interlace questions about physical symptoms with questions about feelings; this greatly increases the effectiveness of the consultation and the quality of the information.
- Treat promptly: symptoms have no more diagnostic usefulness in a situation of advanced disease.
- Make one change at a time (as far as possible).
- Explain changes.
- Include the patient in decision-making.
- Involve the relatives.
- Skilful prescribing.
- Use a drug card.
- Make a plan (e.g. What if she vomits?).
- Monitor regularly (until symptom free).
- Remember emotional factors.
- Reduce or stop drugs whenever possible (Kay 1994).

Pain control

This is managed best by following some simple general rules. First, it is important to try to establish the cause of the pain. Not all pains are due to cancer itself; previous treatment and incidental causes are also important. Investigations may be appropriate, although very ill patients should only be subjected to even simple investigation if it is clear that different results will lead to differences in management.

Assessment of pain

Clear assessment of the pain is required based on the patient's verbal reports. A history of the site/s, area of radiation, duration, aggravating and relieving factors, as well as relevant clinical examination is needed. It is important because continuous pain (visceral and soft tissue) responds to morphine, whereas other types of pain (bone, nerve, colic or non-cancer-related pain, e.g. migraine, angina) need other approaches (Kay 1994).

The pain must be approached with analgesia and with measures designed to improve the woman's ability to endure the pain by restoring her sense of personal worth, and by providing her with opportunities for creative and meaningful activity for as long as possible. Assessment tools may be useful in the assessment of complex or multiple types or sites of pain.

A body chart may be useful for initial assessment because it serves as a communication tool by making the pain 'visible'. It demonstrates the sites of pain, as 80% of patients are thought to have two or more pains (Kay 1994). It should be drawn with or by the patient herself.

Recording pain scores is another simple way to monitor difficult, complex pain control. The woman is asked three times a day to rate the severity of her pain on a scoring system of 0–10, where 0 is no pain at all and 10 is the worst pain imaginable. The scores are reproduced on a pain chart or kept in a patient diary. They may be useful to monitor responses to different treatments, are subjective to the woman's individual experience and allow early changes in pain management to be considered. It is important to

remember that pain is whatever the patient says it is (Twycross 1997b).

Route and frequency of drug administration

When possible, analgesia should be given by mouth. Adequate analgesia is obtained by regular administration of an adequate dose of an appropriate drug at the time intervals which take into account the compound's pharmacokinetics and the individual woman's routine, i.e. time of waking, meal times and sleeping. This reduces the risk of breakthrough pain, but alternative or additional analgesics must be considered and prescribed for breakthrough pain before it actually occurs. Persistent pain requires preventative therapy; analgesics should be given regularly and prophylactically (Twycross 1997b).

Choosing the correct analgesia

The World Health Organization (1986) has suggested a three-stage analgesic ladder for the management of pain. This involves the choice of non-opioid analgesics, mild opioids and strong opioids, each stage involving appropriate use of other non-opioid or adjuvant drugs which may relieve pains of varying type and cause. If a drug fails to relieve the pain, it is important to move up the ladder or/and consider adjuvant drugs, but not to move laterally in the same efficacy group.

The right dose of analgesia for an individual woman is the dose which relieves the pain at night, at rest, during the day and on movement, although this may not be completely possible (Twycross 1997b).

The response to the analgesia must be monitored to ensure that benefits of treatment are maximized and adverse effects (e.g. drowsiness, nausea and constipation) are minimized.

Needs of the Woman Who is Dying

The question most frequently asked is when death will occur. An accurate answer cannot be given and any attempt to do so should be avoided because it causes distress, whether the predicted time is too short or longer than expected. It may be helpful to acknowledge to the patient how hard it must be to accept that healthcare professionals cannot really predict when death will occur.

When death is thought to be imminent, it is important that the patient and carers are kept adequately informed at all times. They may not only wish to know how long it is going to be, but also need to understand what might happen both before, during and after the event.

How people die remains in the memory of those who live on (Saunders and Baines 1989).

A peaceful death is important for the relatives as well as the patient. Families often find it comforting if carers continue to talk to the patient even after unconsciousness. Sedation for terminal agitation or distress should be prompt. It can be allowed to wear off once the patient is settled and any reversible causes have been treated to see if sedation is still necessary (Kay 1996).

As healthcare professionals, we should strive not just for death with dignity but for death with style. For both medical and nursing professionals, this suggests two things: first, that death should not be seen as a failure of medicine; and second, that each doctor and nurse becomes acquainted with death and comfortable in its presence, thus allowing them to participate fully in the patient's experience of death, whatever that means to that particular woman at the time.

The aim is to allow the woman to die as the person she has always been. Sensitive nursing and medical care can give great comfort, and anxieties which may seem too trivial to show to others may be expressed, as nurses and doctors often have great insight into the woman's need; time to share this insight is important.

The terminal phase is characterized by day-to-day deterioration. The common symptoms in the terminal 48 h are shown in Box 48.9. It is beyond the scope of this chapter to discuss the management of each individually.

Bereavement

Bereavement is the complex of emotions felt by those close to the person who is dying or who has died.

Grieving for the loss of someone that we love can be a lonely and frightening experience. Although many people talk about stages of grief, it is actually an unpredictable experience. Feelings can come and go in waves, taking the person forward and then pulling them back. Each person's experience of grief is different, although there are certain thoughts and emotions common to most people.

There is no fixed time scale for grieving; it is a natural process and varies from person to person. However, as an individual gradually faces up to and experiences the pain of grieving, the intensity of feelings will lessen with time and become more bearable. They may always miss the person they have lost and have special memories of them, but it will eventually become possible to live with the loss.

Numbness, shock and disbelief are common in the early days of bereavement. There may be displaced anger, which may be directed inappropriately towards the staff, especially if there appear to have been delays in diagnosis or problems with treatment. The best preparation for bereavement is sympathetic handling of the patient's and family's problems throughout their cancer journey. If anger is displayed, a

Box 48.9 Common symptoms in the last 48 h of life

- Pain
- Incontinence of urine
- Dyspnoea
- Retention
- Nausea and vomiting
- Sweating
- Jerking, twitching
- Plucking
- Confusion

Source: Lichter I, Hunt M 1990 Journal of Palliative Care 6: 7–15. Copyright: Institut universitaire de gériatrie de Montréal.

confrontational or authoritarian approach should be avoided. Questions should be answered honestly and often the real cause of the anger will eventually become apparent.

Immediate expressions of grief vary but the bereaved person may:

- experience numbness and shock at their loss — they may not be able to believe that the person is gone, particularly in the first few weeks;
- think that they have seen or heard the deceased person;
- feel guilty for things done or not done when the person was alive;
- feel angry with the deceased, medical profession or God;
- be relieved that the deceased's suffering is over;
- feel anxious, lonely, exhausted, depressed or despairing;
- search for reasons why they have lost their loved one;
- feel that they are 'going mad' because of the strength of their feelings;
- feel disappointed and/or cheated about plans and expectations that will never be fulfilled;
- have difficulties eating, concentrating and sleeping (due to persistent thoughts of the deceased or nightmares);
- feel unwell or generally run down;
- find everyday situations and relationships difficult to deal with;
- feel that no one understands how they feel;
- find it impossible to think about the future or believe that they could ever be happy again; and
- find that they have changes in sexual drive and desire.

Suggested 'dos' and 'do nots' that may help the bereaved person and their family in their grief are shown below:

Do

- Remember that grief is a normal process.
- Talk about your feelings.
- Resume a normal routine 2–3 weeks after the death.

- Allow children to go back to school and keep their normal activities, such as hobbies or playing sport.
- Allow children to share the grief by expressing their feelings and asking questions. Allow them to attend the funeral if they want to.
- Accept support, both practical and emotional, from family and friends.
- Take care of yourself — eat a balanced diet and take plenty of rest. Illness and accidents are more common when people are going through a traumatic time.
- Allow yourself time to grieve. When you are feeling low, take one day at a time. Grief cannot be hurried or avoided.

Do not

- Cut yourself off from sources of support.
- 'Bottle up' feelings and emotions.
- Dispose of the deceased's belongings until you are ready.
- Make major life decisions or changes in the first year of a bereavement if it can be avoided
- Turn to drugs, alcohol or heavy smoking.

Sources of Support

The bereaved person may feel that they have enough support from family, friends, the church or other organizations. However, feelings may sometimes seem too intense to cope with, or the bereaved may feel that they have no one to talk to who understands. They may find it helpful to talk about their feelings to someone outside their family and friends, or to meet people in a similar situation. This will not take away the pain of their loss, but may help them to cope better.

There are many national support organizations who help and support bereaved individuals.

KEY POINTS

1. Most patients prefer to be told the truth about their condition.
2. Supportive care is not the sole responsibility of one person but the onus lies with the doctor.
3. Staff need to be aware of their own feelings and attitudes to illness and death.
4. Staff must watch and listen carefully and respond to what they observe, rather than have any preconceived ideas about the woman's feelings and needs.
5. Time with the patient must be protected from interruption, and adequate time must be allocated.
6. Accepting the inevitability of mental pain in the patient frees the physician from feelings of inadequacy.
7. There must be no conspiracy of silence in the family, and children need to be included.
8. Many sexual problems can be avoided by simple discussion and encouragement.
9. Analgesia should usually be given orally in regular doses.
10. Intravenous fluids should be avoided in obstruction unless it is clear that surgical correction is a feasible option.
11. Cyclizine and haloperidol are very useful for controlling nausea in obstruction.
12. The GP can play a central role in mobilizing local help.
13. Bereavement affects both family and staff. Both need to mourn.

CLASSIFICATION	768		

Introduction

If the body was divided into specialties by physiological rather than anatomical boundaries, there would be no need for an explanation of urogynaecology. As it is, this specialty represents an interface between gynaecologist and urologist. Physiological events or disease affecting gynaecological organs invariably affect the urinary tract, as they will also sometimes affect the adjacent alimentary system.

It is increasingly recognized that colorectal surgeons have an important role in the management of pelvic floor disorders. The studies of Snooks et al (1984a,b) and Sultan et al (1993) show the traumatic effects of vaginal delivery on the pelvic floor and anal sphincters. Wall and de Lancey (1991) succinctly summarized the need for a holistic approach involving gynaecologists, urologists and colorectal surgeons in the management of pelvic floor disorders.

Following the introduction of subspecialization by the American College of Obstetricians and Gynecologists, the Royal College of Obstetricians and Gynaecologists considered and then recommended subspecialization in 1982. Four subspecialties were created, among them urogynaecology. This comprised the following disorders: congenital anomalies, incontinence, voiding difficulties, urinary fistulae, bladder neuropathy, genital prolapse, urgency and frequency, and urinary tract infection. By common consent, all 'supravesical' conditions and neoplasia arising anywhere in the urinary tract belong to the realm of urology.

To these might now be added disordered bowel motility, descending perineum and rectal prolapse, anal sphincter injuries, rectovaginal fistula, perineal hernia, and faecal and flatal incontinence.

Terminology

As in any developing branch of medicine and science, old terms and definitions have become inadequate. To provide a common language for both clinician and researcher, the

International Continence Society's (1973) Standardization Committee drew up standards of terminology of lower urinary tract function.

Nine reports have now been published, as follows.

1. Standardization of terminology of lower urinary tract dysfunction (Abrams et al 1988).
2. Lower urinary tract rehabilitation techniques: seventh report on the standardization of terminology of lower urinary tract function (Anderson et al 1992).
3. Standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction (Bump et al 1996).
4. Standardization of terminology and assessment of functional characteristics of intestinal urinary reservoirs (Thuroff et al 1996).
5. Standardization of terminology of lower urinary tract function: pressure-flow studies of voiding, urethral resistance and urethral obstruction (Griffiths et al 1997).
6. Standardization of outcome studies in patients with lower urinary tract dysfunction: a report on general principles from the Standardization Committee of the International Continence Society (Mattiasson et al 1998).
7. Outcome measures for research in adult women with symptoms of lower urinary tract dysfunction (Lose et al 1998).
8. Outcome measures for research of lower urinary tract dysfunction in frail older people (Fonda et al 1998).
9. Standardization of terminology in neurogenic lower urinary tract dysfunction (Stöhrer et al 1999).

The term 'stress incontinence' was coined by Sir Eardley Holland in 1928 and meant the loss of urine during physical effort. It came to be used not only as a symptom and sign, but also as a diagnostic term. As the pathophysiology of urinary incontinence became more clearly understood, it was apparent that the term 'stress incontinence' was ambiguous as it could be applied to a symptom, a sign and a

diagnosis; indeed, the symptoms and sign of stress incontinence can be found in most types of incontinence.

Nowadays, the term 'stress incontinence' is retained for the symptom of involuntary loss of urine on physical exertion and the sign of urine loss from the urethra immediately on increase in abdominal pressure. The term 'genuine stress incontinence' was proposed by the International Continence Society in 1976 (Bates et al 1976) to mean the condition of involuntary loss of urine when 'the intravesical pressure exceeds the maximum urethral pressure in the absence of a detrusor contraction'. This condition has a number of synonyms: urethral sphincter incompetence, stress urinary incontinence and anatomical stress incontinence. The authors prefer the term 'urethral sphincter incompetence' because this accurately describes the pathophysiology of this condition.

In a similar way, the term 'dyssynergic detrusor dysfunction' was introduced by Hodgkinson et al in 1963 and other synonyms followed: urge incontinence, uninhibited bladder, bladder instability/unstable bladder and, more recently, overactive bladder. In 1979, the International Continence Society defined an unstable bladder as one 'shown objectively to contract, spontaneously or on provocation during the filling phase, while the patient is attempting to inhibit micturition. Unstable contractions may be asymptomatic and do not necessarily imply a neurological disorder.' The contractions are phasic. Another term, 'low compliance', is used to mean a gradual increase in detrusor pressure without a subsequent decrease during bladder filling. The term 'neurogenic detrusor overactivity' is used for phasic uninhibited contractions when there is objective evidence of a relevant neurological disorder. Terms to be avoided include 'hyper-tonic', 'spastic' and 'automatic'.

Classification

Congenital anomalies (see Chapter 1)

The subject of congenital anomalies reaffirms the principle that a lesion affects multiple systems. These often present to the urologist as a primary urological problem (e.g. bladder exstrophy, horseshoe kidney). The gynaecologist's expertise lies in the area of diagnosis and management of dubious sexuality or later, when reconstructive surgery may be required for epispadias or haematocolpos.

Incontinence

Urinary incontinence forms the major proportion of urogynaecology. It is defined by the International Continence Society as 'an involuntary loss of urine which is objectively demonstrable and a social or hygienic problem'.

Incontinence is considered to be involuntary; for two categories of patients, further explanation is needed. In a child under 3 years of age, control of continence has not yet developed; however, careful observation shows that the normal child is dry between involuntary voids, whereas the incontinent child is wet the whole time. On the other hand, the mentally frail or elderly demented patient may be incontinent because she has lost her social consciousness and appreciation of the need to be dry.

The social isolation caused by incontinence is demonstrated by 25% of patients delaying for more than 5 years before seeking advice, owing to embarrassment (Norton et al 1988). Ostracism and rejection by relatives may lead to an elderly patient being institutionalized solely because of incontinence; paradoxically, some allegedly 'caring' institutions will not accept an elderly patient if she is incontinent.

It is now accepted that incontinence should be objectively demonstrable using urodynamic studies, which will define the cause and detect other conditions such as voiding disorders and overactive bladder.

The hygienic aspect of incontinence occupies some 25% of nursing time in hospitals. Unless managed, urinary odour is offensive to both patient and relatives alike.

Incontinence may be divided into urethral and extra-urethral conditions (Figure 49.1).

Urethral conditions

Urethral sphincter incompetence (urodynamic stress incontinence)

This is the most common urethral condition, has several causes and can present from childhood (see Chapter 52). The original classification of type 1, 2 and 3 is facile. It is realistic to acknowledge that whilst only some patients have 'urethral hypermobility', all will have some degree of sphincter incompetence, otherwise they would not leak. Type 3 is gross incontinence with a maximum urethral closure pressure below 20 cmH₂O (more usefully termed 'intrinsic sphincter defect'). Conventional bladder neck elevating surgery or even midurethral support surgery is unlikely to succeed in type 3 patients; what is required is something to restore urethral pressure, such as an artificial urinary sphincter. For the vast majority (i.e. old type 1 and 2), either a bladder neck elevating procedure, such as a colposuspension or sling, or a midurethral support procedure, such as a

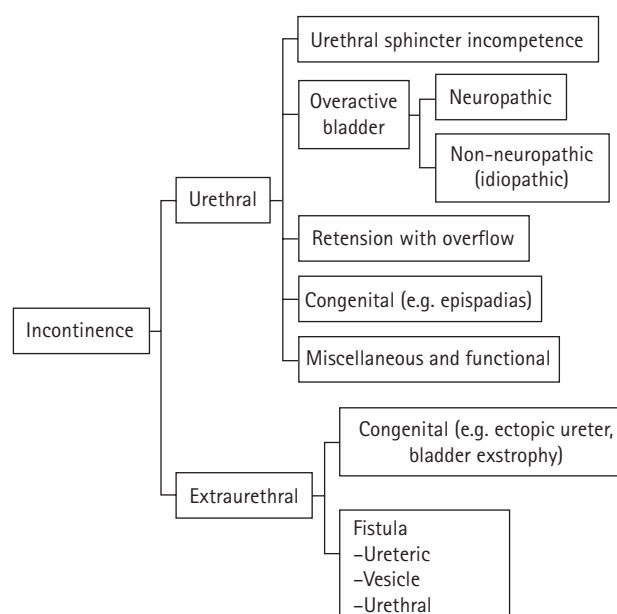

Figure 49.1 Classification of incontinence.

tension-free vaginal tape procedure, will likely suffice. The latter has shown that lack of midurethral support is a significant cause of sphincter incompetence.

Overactive bladder (see Chapter 53)

Depending on its cause, this may be subdivided into neuro-pathic or idiopathic. Some patients with overactive bladder and a competent sphincter mechanism may remain dry. If, however, there is coexistent sphincteric incompetence ('mixed incontinence'), the patient may complain of stress incontinence and urge incontinence.

Urinary retention and overflow (see Chapter 54)

This may be acute or chronic; the former is usually sudden in onset and painful. There may be an obvious cause, such as an impacted pelvic mass. Chronic retention, on the other hand, is often painless, insidious and frequently undetected, so errors in diagnosis are often made. It occurs more commonly in the elderly as a result of neuropathy (e.g. peripheral diabetic neuropathy or stenosis of the lumbar spinal canal).

Congenital disorders

Epispadias is usually detected during childhood, but occasionally it is not diagnosed until adult life.

Miscellaneous

These causes include urethral diverticulum, urinary tract infection (temporary and most common in the elderly), faecal impaction, drugs (such as α -adrenergic blocking agents) and functional disorders. These are rare; the patient should be fully investigated and all the above causes excluded before this diagnosis is made. The loss of social awareness of the need to be continent is usually associated with dementia or a space-occupying lesion of the frontal cortex.

Extraurethral conditions

These may be divided into congenital and acquired. Extra-urethral conditions may be distinguished from urethral conditions by the symptom of continuous incontinence. The congenital disorders include ectopic ureter and bladder exstrophy. Acquired conditions include urinary fistulae, which in the Western world are largely iatrogenic, the majority occurring after abdominal hysterectomy for benign conditions (see Chapter 57). Other causes include pelvic carcinoma and its attendant surgery or radiotherapy. In the developing world, obstetrical causes such as obstructed labour with an impacted vertex are more common. If the fistula is small, skill and patience are required to detect it.

Voiding difficulties (see Chapter 54)

These are uncommon in the female and are frequently undiagnosed. If untreated, they can lead to recurrent urinary tract infection, or acute or chronic retention following otherwise successful bladder neck surgery for incontinence.

Urinary fistulae

These have already been referred to and are dealt with at length in Chapter 57.

Bladder neuropathy

This is rightfully dealt with by the urologist, but it is important for the gynaecologist to be aware of and to recognize these disorders.

Genital prolapse

Prolapse should not be considered in isolation as it is sometimes associated with urethral sphincter incompetence, or with perineal descent and faecal incontinence (see Chapter 55). The latter conditions represent an important interface with the colorectal surgeon.

Urgency and frequency

These symptoms can, of course, be part of a urinary disease process, such as urinary tract infection or overactive bladder, but can often present as single or combined symptoms in the absence of an obvious pathology (see Chapter 56).

Urinary tract infection (see Chapter 58)

This is of common interest to the obstetrician/gynaecologist, urologist and nephrologist, and the experience of all three may be required for difficult cases. However, the majority of patients are treated by the general practitioner without referral to hospital, although urinary tract infection is frequently unproven. Inadequate treatment during pregnancy can lead to acute pyelonephritis and abortion, and if neglected in later life, can lead to chronic pyelonephritis, hypertension and later renal failure.

Conclusion

This classification is an introduction to urogynaecology and the ensuing chapters will provide more detail. For more specialized reading, a list of selected books is given after the references.

KEY POINTS

1. Trauma, denervation and the menopause affect the whole of the pelvic floor.
2. Urogynaecology needs to include rectal prolapse, anal sphincter injury and rectovaginal fistula.
3. Standardized terminology and methodology, as suggested by the International Continence Society, should be used.
4. Incontinence has a variety of causes which need urodynamic studies for their accurate diagnosis.
5. Stress incontinence is a symptom and a sign, not a diagnosis.

Urinary Incontinence

Introduction

Urinary incontinence may be defined as a condition in which an involuntary loss of urine is a social or hygienic problem and is objectively demonstrable. Therefore, continence is the ability to retain urine within the bladder between voluntary acts of micturition. In order to fully comprehend the pathological processes which lead to the development of urinary incontinence, a clear understanding of normal mechanisms for the maintenance of continence is fundamental.

Anatomy of the lower urinary tract

The bladder

The bladder consists of three layers of smooth muscle, known collectively as the 'detrusor', which functions as one syncytial mass with the exception of the trigone. The outer smooth muscle layer is oriented longitudinally, the middle layer is oriented circularly and the inner layer is oriented longitudinally.

Histochemically, the detrusor muscle has been shown to be rich in acetylcholinesterase by virtue of its rich cholinergic parasympathetic nerve supply. In contrast, the trigone only comprises two layers of smooth muscle. The inner layer is similar to the rest of the detrusor, but the outer layer consists of smooth muscle bundles with a sparse parasympathetic nerve supply. The outer layer extends to, and is continuous with, the proximal urethra and the distal portion of the ureter, where it may have a role in preventing ureteric reflux. The smooth muscle that forms the bladder neck is separate from the detrusor, with little or no sphincteric effect. Two or three layers of transitional epithelia cover the detrusor and secrete a protein on to their luminal surface that forms a watertight blood-bladder barrier. When empty, the urothelium relaxes into numerous folds or rugae.

The urethra

The normal female urethra is 30–50 mm in length. It comprises smooth and striated muscle. The smooth muscle is continuous with that of the detrusor, but has minimal parasympathetic innervation and little sphincteric effect in contrast to the profusion of acetylcholinesterase within the detrusor cells. The external urethral sphincter (rhabdosphincter) is one of two striated muscle components surrounding the urethra. Its fibres are bulked anteriorly at the midurethral level, are slow twitch in nature and are involved in maintaining continence at rest. The second striated muscle component is the periurethral portion of the levator ani, which is separated from the external urethral sphincter by a connective tissue septum. The fibres are bulked anterolaterally at a lower level than the external urethral sphincter, are fast twitch in nature and are involved in maintaining continence under stress.

The mucosa of the urethra is lined by pseudostratified transitional epithelia proximally, changing to non-keratinized stratified squamous epithelia distally. The junction between the two cell types alters with age and oestrogenic status, which may affect urinary symptoms. In young females, the submucosa has a rich venous supply which engorges the tissues, helping to close the urethra. This ceases after the menopause, and may be involved in the development of stress incontinence later in life due to poor urethral closure.

The pelvic floor

For the context of this chapter, the pelvic floor structures that will be described are the levator ani muscles, the endopelvic fascia and condensations of this fascia which form the ligaments. The levator ani muscles are often described as funnel-shaped structures, but in-vivo imaging has revealed that they are, in fact, more horizontal. The fibres of each side pass downwards and inwards. The two muscles, one on each side, constitute the pelvic diaphragm. Defects in the levator ani allow the urethra, vagina and

Figure 50.1 The pelvic floor musculature and ligaments.

rectum to pass. The levator ani is subdivided into the pubococcygeus, iliococcygeus and coccygeus. The pubococcygeus arises anteriorly from the posterior aspect of the pubic bone and from the anterior portion of the arcus tendineus (white line), which is a condensation of the obturator internus fascia. The medial fibres of the pubococcygeus merge with the fibres of the vagina and perineal body, and have been given various names such as puborectalis, pubourethralis and pubovaginalis. The iliococcygeus arises from the remainder of the arcus tendineus, partly overlapping the pubococcygeus on its perineal surface and extending to the medial surface of the ischial spine. The coccygeus or ischiococcygeus is a rudimentary muscle arising from the tip of the ischial spine, and quite often constitutes only a few muscle fibres on the sacrospinous ligament. Posteriorly, the muscles of the levator ani or pelvic diaphragm insert into the sides of the coccyx and the anococcygeal raphe, which is formed by the interdigitation of muscle fibres from either side. The most medial fibres of the pubococcygeus that pass round the rectum at the anorectal junction form the puborectalis muscle (Figure 50.1).

The endopelvic fascia invests all the structures that lie within the pelvis and is mainly composed of loose areolar tissue, although smooth muscle cells have been identified. The layer between the bladder, urethra and vagina is termed the 'vesicovaginal fascia', and the layer between the vagina and rectum is known as the 'rectovaginal fascia' or 'rectovaginal septum'. Laterally, both these layers attach to a condensation of fascia known as the 'arcus tendineus fasciae pelvis'. This is a condensation of the endopelvic fascia which runs from the posterior part of the pubic ramus to the ischial

spine, and attaches to the stronger underlying obturator internus muscle fascia. The urethra has an intimate attachment to the lower one-third of the vagina, and therefore the supports for these structures are identical. The urethra has a further condensation of the endopelvic fascia which attaches to the symphysis pubis. These are known as the 'pubourethral ligaments' and lie at the midportion of the urethra. They are fairly loose attachments, and allow movement of the bladder neck during straining and also by voluntary contraction of the levator ani muscles.

The uterus, cervix and upper third of the vagina are attached to the pelvic side wall by broad condensations of endopelvic fascia with a high content of smooth muscle cells, known as the 'cardinal and uterosacral ligaments'. These ligaments originate from the region of the greater sciatic foramen and the lateral aspects of the sacrum. In the erect position, these ligaments run almost vertically and suspend their attached structures.

The levator ani muscles, ligaments and endopelvic fascia work in synergy. If any of these structures is not intact, the mechanisms of support and continence may be affected.

Innervation of the bladder and urethra

The bladder has a rich parasympathetic nerve supply (Figure 50.2). The postganglionic cell bodies lie either in the bladder wall or pelvic plexuses, innervated by preganglionic fibres that originate from cell bodies in the grey columns of S2–4. There is little sympathetic innervation of the bladder, although greater quantities of noradrenergic terminals can be detected in the bladder neck or trigone. Noradrenergic

Figure 50.2 The major innervation pathways at the pelvic level that are basic to control of micturition and continence.

effects can be either inhibitory or excitatory, depending on the receptor type present.

- α -Receptors, located predominantly in the bladder base, cause detrusor contraction. They can be manipulated with limited success with α -adrenergic agonists to treat mild stress incontinence.
- β -Receptors which cause detrusor relaxation are found in the dome of the bladder.

The cell bodies of the sympathetic nerves originate in the grey matter of T10–L2, and pass through the sympathetic chain via the lumbar splanchnic nerve and left and right hypogastric nerves to the pelvic plexus. It is thought that the sympathetic nervous system exerts its effects by inhibiting the parasympathetic nervous system rather than by direct action. The visceral nerve afferents pass along the sacral and thoracolumbar visceral efferents, relaying sensations of touch, pain and distension. However, transection has little or no effect on micturition. The urethra possesses similar autonomic innervation. Parasympathetic efferents cause contraction but the functional significance of this remains in doubt. There is no obvious sphincteric function, but contraction produces shortening and widening of the urethra along with detrusor contraction during micturition. Sympathetic efferents innervate the predominantly α -adrenoreceptors.

Innervation of striated muscle

The rhabdosphincter muscle is supplied via the pelvic splanchnic nerves travelling with the parasympathetic fibres

to the intrinsic smooth muscle of the urethra. This is analogous to the puborectalis muscle.

The extrinsic periurethral muscle of the levator ani is innervated by motor fibres of the perineal branch of the pudendal nerve. This is in common with the external anal sphincter (EAS). The pudendal nerve also supplies the striated elements of the levator ani on both sides, and there are associated somatic afferent fibres which travel with the pudendal nerves. They ascend via the dorsal columns to convey proprioception from the pelvic floor.

Central nervous control of continence

The connections of the lower urinary tract within the central nervous system are complex (Figure 50.3). There are many discrete areas which influence micturition, and these have been identified within the cerebral cortex, in the superior frontal and anterior cingulate gyri of the frontal lobe and the paracentral lobule; within the cerebellum, in the anterior vermis and fastigial nucleus; and in subcortical areas, including the thalamus, the basal ganglia, the limbic system, the hypothalamus and discrete areas of the mesencephalic pontine medullary reticular formation. The full function and interactions of these various areas are incompletely understood, although the effects of ablation and tumour growth in humans and stimulation studies in animals have given some insights.

The centres within the cerebral cortex are important in the perception of sensation in the lower urinary tract, and the inhibition and subsequent initiation of voiding. Lesions in the superior frontal gyrus and the adjacent anterior cin-

Figure 50.3 The interaction of the nervous system in micturition. Locations of possible nervous lesions are denoted by numbers. 1, lesions isolating superior frontal gyrus will prevent voluntary postponement of voiding; 2, lesions isolating paracentral lobule, often with hemiparesis, will cause spasticity of urethral sphincter and retention; 3, pathways of sensation are not known accurately; in theory, isolated lesion of sensation above brainstem would lead to unconscious incontinence, and defective conduction of sensory information would explain enuresis; 4, lesions above brainstem centres lead to involuntary voiding that is coordinated with sphincter relaxation; 5, lesions below brainstem centres but above the sacral spinal cord lead, after a period of bladder paralysis, to involuntary 'reflex' voiding that is not coordinated with sphincter relaxation.

gulate gyrus reduce or abolish both the conscious and unconscious inhibition of the micturition reflex. The bladder tends to empty at low functional capacity. Sometimes, the patient is aware of the sensation of urgency; sometimes, micturition may be entirely unconscious. These areas, which have been localized by functional magnetic resonance imaging (MRI), are supplied by the anterior cerebral and pericallosal arteries; spasm or occlusion of these arteries produces incontinence.

Localized lesions more posteriorly in the paracentral lobule may produce retention rather than incontinence because of the combination of impaired sensation and spasticity of the pelvic floor.

The thalamus is the principal relay centre for pathways projecting to the cerebral cortex, and ascending pathways activated by bladder and urethral receptors synapse on neurones in specific thalamic nuclei which have reciprocal connections with the cortex. Electrical stimulation of the basal ganglia in animals leads to suppression of the detrusor reflex, whereas ablation has resulted in detrusor hyperreflexia; patients with Parkinsonism are commonly shown to have detrusor instability on cystometric examination.

Within the pontine reticular formation are two closely related areas with inhibitory and excitatory effects on the sacral micturition centre in the conus medullaris. Lesions of the cord below this level always lead to incoordinate voiding with a failure of urethral relaxation during detrusor contraction; lesions above this level may be associated with normal although involuntary micturition.

The mechanism of urinary continence

The mechanism of urinary continence is a complex dynamic process which relies on intact fascia, ligaments and muscles with their accompanying nerve and vascular supply. It relies on maximum urethral pressure being higher than maximum detrusor pressure. There are special features of physiology and anatomy that contribute to the maintenance of a low detrusor pressure, and adequate urethral closure and positioning. These features are discussed below.

Bladder

An intravesical pressure that exceeds urethral pressure will lead to incontinence. There are a number of factors which maintain a low intravesical pressure.

The hydrostatic pressure at the bladder neck

Any fluid within the bladder will itself have a pressure. This is due to a vertical gravitational pressure gradient. For clinical purposes, the intravesical pressure defines the pressure in the bladder with respect to atmospheric pressure measured at the level of the upper border of the symphysis pubis. This pressure works against the mechanisms that produce urethral closure, and very rarely amounts to more than 10 cmH₂O.

Transmission of intra-abdominal pressure

The bladder is normally an intra-abdominal organ and is subject to the pressures of adjacent organs and abdominal pressure. The pressures are normally equally transmitted to the bladder, the bladder neck and proximal areas of the urethra, and this helps to maintain continence.

Tension in the bladder wall

Due to higher control of the basic visceral reflexes, the bladder does not contract in response to stretch receptors within the bladder wall. This and the actual ability of the bladder to be compliant (i.e. to allow for a large rise in volume and little rise in pressure) make it an ideal storage organ.

Urethra

There are several components of urethral function that are necessary to maintain good urethral closure.

The hermetic seal

The vascularity in the submucosal urethral plexuses has been mentioned above, and there are also secretions that allow this seal to be maintained. This may fail after the menopause.

The intrinsic smooth and striated muscles and the extrinsic striated muscles

The intrinsic smooth and striated muscles exert a constant pressure from their constant tone, and the extrinsic striated muscle contracts during moments of stress to maintain urethral closure. It has been estimated from urethral pressure studies that resting urethral pressure is one-third due to external striated muscle effects, one-third due to smooth muscle effects and one-third due to its vascular supply. The highest pressure is found at the midurethral point.

Figure 50.4 Fascial breaks.

Urethral support

From cadaveric studies, ultrasound and MRI, it is postulated that the urethra is supported by a hammock (Figure 50.4). This hammock is contributed to by its intimate relationship with the vagina, and the pubocervical fascia that lies between them and attaches laterally to the arcus tendineus fascia pelvis, which attaches to muscle fascia and which are in connection with the levator ani muscles themselves. During any rise in abdominal pressure, these may cause compression of the urethra against the anterior vaginal wall. In this model, it is the stability of the supporting structures rather than the height of the urethra that determines stress continence. In an individual with a firm supportive layer, the urethral compression can be compared with the way that the flow of water through a garden hose can be stopped by stepping on it and compressing it against concrete. The pubourethral ligaments also contribute to midurethral support.

Normal micturition cycle

Filling and storage phase

The bladder normally fills with urine by a series of peristaltic contractions at a rate of between 0.5 and 5 ml/min. Under these conditions, the bladder pressure only increases minimally. Urethral closure is maintained by the three mechanisms mentioned above. During the early stages of bladder filling, proprioceptive afferent impulses from the stretch receptors within the bladder wall pass via the pelvic nerves to sacral dorsal roots S2–4. These impulses ascend in the cord via the lateral spinothalamic tracts, and any detrusor motor response is inhibited by descending impulses from higher centres. As bladder filling continues, further afferent impulses ascend to the cerebral cortex, and eventually a first

sensation to desire is appreciated. This is usually at approximately half of functional bladder capacity. The impulses increase as volume increases and reinforce conscious inhibition; micturition occurs when a suitable site and posture for micturition is found. At this time, in addition to the cortical suppression of detrusor activity, there may also be a voluntary pelvic floor contraction in an attempt to improve urethral closure.

Initiation phase

When a suitable time, site and posture for micturition have been selected, the process of voiding commences. Relaxation of the pelvic floor occurs early in the process of initiation and micturition. This can be observed radiologically and also by performing electromyography where an electrical silence is recorded. It is likely that a simultaneous relaxation of the intrinsic striated muscle also occurs, since a marked decrease in intraurethral pressure is seen before the intravesical pressure rises. A few seconds later, the descending inhibitory influences are suppressed, allowing rapid discharge of efferent parasympathetic impulses via the pelvic nerves to cause detrusor contraction at the bladder neck. In addition, there is probably efferent sympathetic discharge encouraging urethral relaxation.

Voiding phase

When the decreasing urethral pressure and increasing intravesical pressure equate, urine flow will commence. As bladder emptying occurs, the radius of the bladder decreases. However, the pressure remains constant during voiding, and therefore it is likely that the tension of the wall decreases as voiding continues. If micturition is voluntarily interrupted midstream by contraction of the periurethral striated muscle, the urethral pressure rises rapidly and urine flow stops. The

detrusor is much slower to relax and therefore goes on contracting against the sphincter, and an isometric contraction occurs. At the end of micturition, the intravesical pressure gradually decreases as urine flow diminishes. The pelvic floor and intrinsic striated muscle are contracted, flow is interrupted in the mid urethra, and a process of milkback occurs where a few drops of urine are forced back into the bladder as urethral closure occurs in a cephalad direction.

Pathophysiology of urinary incontinence

The pathophysiology of major causes of incontinence is discussed in some detail in the following chapters. A few general principles are considered here.

If the lower urinary tract is intact, urine flow can only occur when the intravesical pressure exceeds the maximum urethral pressure or when the maximum urethral pressure becomes negative. Causes of this are discussed in later chapters but may be largely due to childbirth, with direct mechanical injury to the supports including muscle and connective tissue, and following denervation injury to those muscles. Ageing also plays a part, as does pelvic floor surgery and radiotherapy. Incontinence, therefore, may occur as a result of:

- a decrease in urethral pressure associated with an increase in intravesical pressure. This can occur during normal voiding or in cases of detrusor instability (Figure 50.5A);
- an increase in intravesical pressure associated with an increase in urethral pressure where the latter rise is insufficient to maintain a positive closure pressure. This may be the case in detrusor instability with associated detrusor sphincter dyssynergia (Figure 50.5B);
- an abnormally steep rise in detrusor pressure during bladder filling, suggesting impaired bladder compliance. This can occur after pelvic irradiation or with conditions that cause chronic inflammation such as tuberculosis or interstitial cystitis (Figure 50.5C);
- loss of urethral pressure alone. This can occur in urethral instability and also in women who have urethral insufficiency or, as it is otherwise termed, 'intrinsic sphincter deficiency'. This can commonly occur in the menopause, or after radiotherapy or surgery (Figure 50.5D); or
- during periods of stress, the intravesical pressure rises to a greater extent than the intraurethral pressure. This is usually due to a lack of urethral support, or an abnormally positioned bladder neck and proximal urethra where equal pressure transmission does not occur (Figure 50.5E).

Effect of continence surgery on mechanisms of continence

There are many operations for stress incontinence and the mechanism of their actions is debated. Operations such as the Burch colposuspension and Marshall–Marchetti–Krantz elevate the bladder neck, and this is assumed to restore it to its zone of equal pressure transmission. This has been shown using pressure transmission ratios, where increased pressure is transmitted to the proximal quartile of the urethra, but there are obviously obstructive components that also con-

tribute. Bladder neck injectables have been used to increase urethral length, allowing better transmission to the proximal urethra. Finally, tension-free vaginal tape and its evolutionary descendants obturator and single incision tapes are thought to work by increasing the support of the urethra in the midurethral zone, rather than influencing bladder neck position.

Anal Incontinence

Definition

Faecal incontinence is defined as 'the involuntary or inappropriate passage of faeces' (Royal College of Physicians 1995). This definition, however, is incomplete as it may not include incontinence to flatus. Therefore, many adopt the term 'anal incontinence' to include flatus. Furthermore, this definition includes transient episodes of incontinence that may be experienced following a bout of gastrointestinal upset, and therefore a definition similar to that proposed by the International Continence Society for urinary incontinence may be more appropriate; namely, anal incontinence is the involuntary loss of flatus or faeces that is a social or hygienic problem.

Prevalence of anal incontinence

The estimated community prevalence of faecal incontinence is 4.2 per 1000 in men aged 15–64 years, 10.9 per 1000 in men aged 65 years or over, 1.7 per 1000 in women aged 15–64 years and 13.3 per 1000 in women aged 65 years or over. In residential homes for the elderly, the incidence was found to be 10.3% but may approach 60% in the elderly. Although the incidence of faecal incontinence in 45-year-old women is eight times higher than that in men of the same age, its prevalence has not been accurately assessed in the younger age groups. Even a minor degree of faecal incontinence can be very distressing and is a cause of great embarrassment; therefore, very few admit to it and seek medical assistance. In one study, half the patients referred to a gastrointestinal clinic complaining of diarrhoea were incontinent, but less than half of them volunteered this information. Moreover, clinicians may not enquire or document this symptom, and therefore the true prevalence of faecal incontinence can be grossly underestimated. A validated scoring system would therefore be more representative for epidemiological and research purposes. The Wexner scoring system is very popular and includes the need to wear a pad and alteration in lifestyle (Table 50.1). A modified version of the Wexner score has also been introduced to include faecal urgency, the ability to defer defaecation and the use of antidiarrhoeal medications.

The anal sphincter mechanism

The puborectalis and the external anal sphincter

Proximally, the EAS lies in contiguity with the posterior half of the puborectalis; distally, it merges with the perianal skin. Like the levator ani, it is primarily composed of striated muscle. There is lack of consistency in the literature with regard to the structural subdivisions of the EAS.

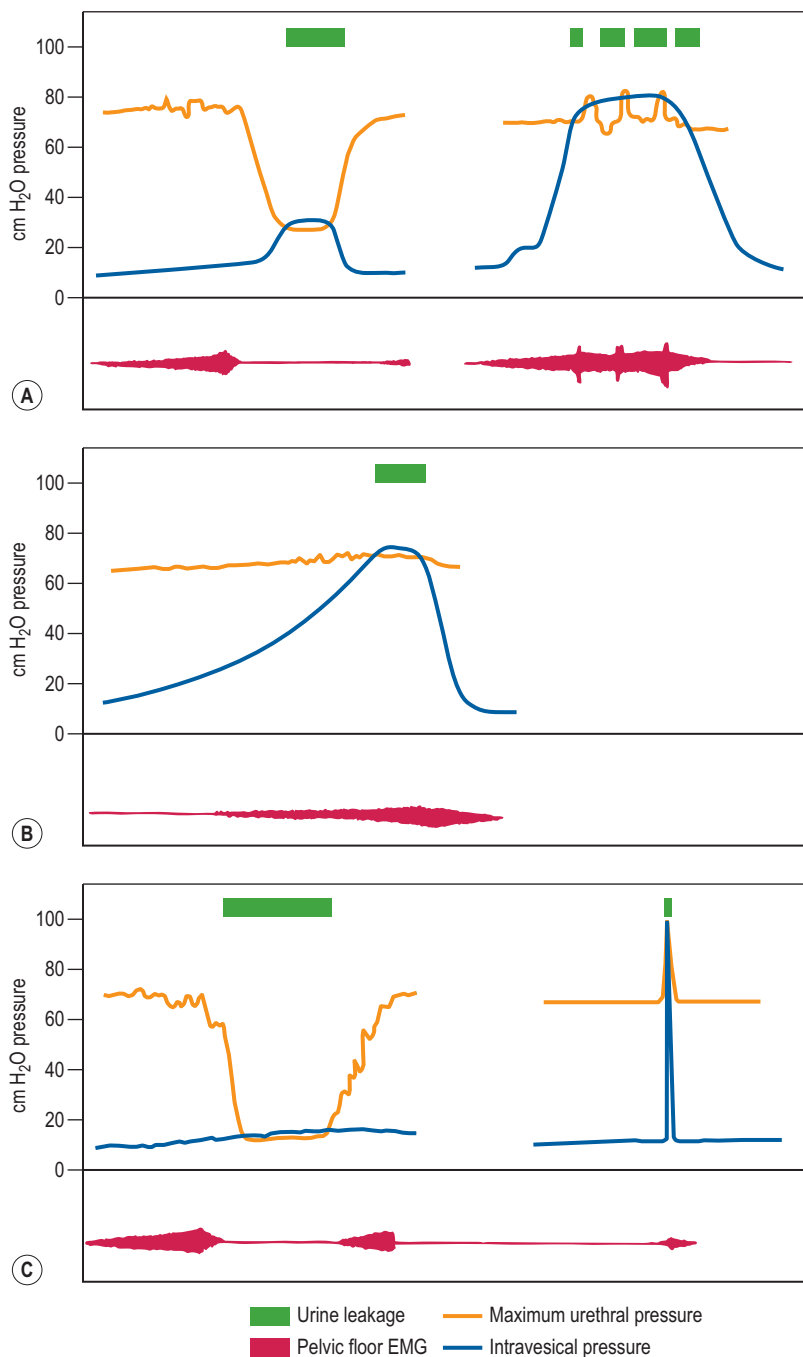

Figure 50.5 Mechanisms of urinary incontinence showing changes in urethral and intravesical pressure and pelvic floor electromyogram (EMG) at various stages of bladder filling in different types of incontinence. (A) Normal voiding or detrusor instability. (B) Detrusor instability with detrusor sphincter dyssynergia. (C) Impaired bladder compliance. (D) Urethral instability. (E) Genuine stress incontinence.

Some authors describe it as one structure, while others have subdivided it into two or even three components: the subcutaneous and deep EAS as annular muscles not attached to the coccyx, and the superficial EAS (middle layer) as being elliptical with fibres running anteroposteriorly from the perineal body to the coccyx and the anococcygeal raphe (Figure 50.6). The deep EAS has anterior fibres which cross over to the opposite side and combine with the superficial transverse perinei attaching to the ascending ramus of the ischium. Electrophysiological techniques have shown that the motor supply of the puborectalis is via direct branches

of the sacral nerves (S3 and S4), and that of the EAS is via the pudendal nerve (S2–4). This supports the contention that the puborectalis is part of the levator ani and separate from the anal sphincter. Nevertheless, close cohesion between these muscles would seem to be essential because without it, peristalsis would pull the rectum upwards and over its contents without expelling them through the anus. Frustration in attempts to identify these subdivisions of the EAS led some authors to propose that the EAS is, in fact, a single structure with no real subdivision. As these subdivisions are not identified during surgery, they do not appear

Table 50.1 The Wexner score

Type of incontinence	Frequency				
	Never	Rarely	Sometimes	Usually	Always
Solid	0	1	2	3	4
Liquid	0	1	2	3	4
Gas	0	1	2	3	4
Wears pad	0	1	2	3	4
Lifestyle alteration	0	1	2	3	4

Never: 0.
 Rarely: <1/month.
 Sometimes: <1/week, ≤1/month.
 Usually: <1/day, ≤1/week.
 Always: ≤1/day.
 0 = perfect continence.
 20 = complete incontinence.

**Figure 50.6** The anal sphincter mechanism showing the puborectalis and external anal sphincter (EAS), the longitudinal muscle, and the internal anal sphincter (IAS).

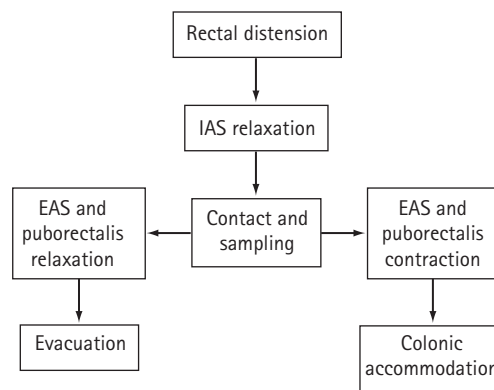

to be clinically relevant. However, a clear understanding of normal anatomy and variants is important during imaging (ultrasound and MRI) of the anal sphincter in order to avoid misinterpretation.

The longitudinal muscle

The longitudinal muscle of the anal canal is a direct continuation of the smooth longitudinal muscle of the rectum. Between the lower border of the internal anal sphincter (IAS) and the upper border of the subcutaneous EAS, it attaches to the anal skin to form the anal intermuscular septum. Many of the fibres then pass outwards, traversing the subcutaneous EAS to insert into the perianal skin to form the corrugator cutis ani. The functional significance of this muscle is unknown.

The internal anal sphincter

The IAS is continuous with the inner circular smooth muscle of the rectum, and terminates in a sharply defined, thickened, rounded lower margin, separated from the subcutaneous

**Figure 50.7** The mechanism of defaecation. EAS, external anal sphincter; IAS, internal anal sphincter.

ous EAS by the anal intermuscular septum. The IAS measures approximately 3 mm in length and 5 mm in thickness. It is tonically active and under autonomic control, namely excitatory (sympathetic L1–2) and inhibitory (parasympathetic S2–4).

The defaecation cycle

The main reservoir for faeces is the transverse colon, and the rectum is usually empty. Although the rectum has a poor supply of intraepithelial receptors, it is sensitive to distension. The first sensation of rectal filling occurs at a volume of 50 ml, with a maximum tolerated volume of 200 ml. Depending on various factors such as gut motility and stool consistency, colonic contents are delivered at a variable rate to the rectum.

Following rectal distension with either faeces or flatus, the internal sphincter relaxes to allow sampling of rectal contents to take place by the specialized sensory epithelium of the anal canal (Figure 50.7). This relaxation is mediated via myenteric connections modulated by the autonomic nervous system, and is known as the 'rectoanal inhibitory reflex'

Figure 50.8 The mechanism of anal continence.

(RAIR). If it is socially convenient, the puborectalis and external sphincter relax and evacuation occurs. If the time for evacuation is inappropriate, EAS contraction extends the period of continence to allow the compliance mechanisms within the colon to make adjustments in order to accommodate the increased rectal volume. Thereafter, the stretch receptors are no longer activated and afferent stimuli are abolished, together with the sensation of faecal urgency.

The factors contributing to the mechanism of incontinence will be discussed in detail below.

Anal continence mechanisms

The mechanism that maintains continence is complex and affected by various factors such as mental function, lack of a compliant rectal reservoir, changes in stool consistency and volume, diminished anorectal sensation and enhanced colonic transit (Figure 50.8). However, analogous to urinary continence, anal continence can be maintained provided that the anal pressure exceeds the rectal pressure. As shown in Figure 50.6, the ultimate barrier to rectal contents is provided by the puborectalis sling and anal sphincters. An increased volume of liquid stool coupled with rapid colonic transit may overwhelm the compliant rectal reservoir. Therefore, if the rectum is able to function effectively as a rectal reservoir and in the presence of normal stool consistency, faecal incontinence can usually be attributed to defective function of the anal sphincter complex.

The physiological role of various components of this complex in maintaining continence will be considered separately.

The puborectalis muscle and the anorectal angle

The anorectal angle is formed by the anteriorly directed pull of the puborectalis. The angle varies from 60° to 105° at rest; during defaecation, the angle straightens, allowing the rectum to empty. Two theories have been proposed to explain how the anatomical angulation at the anorectal junction may contribute to maintain continence. The first is the 'flutter' valve, which is created as the rectum passes through the slit-like aperture in the pelvic floor caused by the forward pull of the puborectalis; a rise in intra-abdominal pressure would create a high-pressure zone and result in apposition of the rectal walls at the anorectal junction. The second is the flap valve theory; contraction of the puborectalis creates an acute anorectal angle, and intra-abdom-

inal forces compress the anterior rectal wall against the upper anal canal. However, both these theories have lost credibility; for a flutter valve to produce such a high-pressure zone, intra-abdominal forces would have to be applied below the pelvic floor. Moreover, both theories would account for rectal pressures in excess of anal canal pressures without evacuation of rectal contents. As rectal pressures have been shown to be consistently lower than anal pressures in healthy subjects, continence must be sphincteric and not valvular.

The puborectalis is considered by some to be the most important muscle in maintaining continence. In children with congenital anomalies and absence of the anal sphincter, a high degree of continence can be maintained with the puborectalis. However, posterior division of the puborectalis in the treatment of chronic constipation made no difference to the anorectal angle, and was not associated with incontinence of solid stool. Furthermore, following successful postanal repair for faecal incontinence, no significant change was observed in the anorectal angle. The role of the anorectal angle in maintaining continence therefore remains controversial.

The puborectalis muscle functions in concert with the EAS, and it is probable that if damage occurs to one muscle, the other may compensate functionally. Faecal incontinence may ensue if, in addition, other factors in the continence mechanism (see below) are compromised or if the remaining muscle cannot compensate adequately.

Internal anal sphincter

There are conflicting opinions on the role of the IAS in maintaining continence. As 70% of the resting tone is contributed by the IAS, it is a major factor in keeping the anal canal closed at rest. This is supported by the finding that symptoms of incontinence can develop in up to 40% of cases following lateral internal anal sphincterotomy. Faecal incontinence has also been reported following anal dilatation, with sonographic evidence of internal sphincter disruption and a reduced resting pressure.

Ultrastructural changes have been identified in the morphology of the internal sphincter of patients suffering from neurogenic faecal incontinence. Although these changes are probably not the primary cause of faecal incontinence, they may have some relevance to IAS function. In addition, abnormalities of adrenergic innervation with a diminished sensitivity of the IAS to α -adrenergic agents *in vitro* have been demonstrated in patients with idiopathic faecal incontinence. These changes could be attributed to an intrinsic degeneration of the muscle and its receptors, or to simultaneous direct injury to the striated muscle of the pelvic floor.

The rectoanal inhibitory reflex

The RAIR or rectosphincteric reflex is a transient relaxation of the IAS when the rectum is distended. This response has been shown to persist in patients with cauda equina lesions and after complete transection of the spinal cord, indicating that it occurs independently of central control. It appears that the RAIR is mediated by intramural myenteric neurones because topical anaesthesia of the rectal mucosa blocks the reflex, and it is absent in patients with Hirschsprung's disease.

The RAIR causes equalization of rectal and upper canal resting pressures, and allows rectal contents to enter the anal canal. The contents are then analysed by the specialized sensory epithelium in the anal canal (sampling reflex). This is accompanied by a reflex contraction of the external sphincter and puborectalis (inflation reflex), which temporarily maintains the high-pressure zone in the anal canal until either evacuation occurs or the anal contents are pushed back into the rectum. The sampling reflex occurs as a normal physiological process about seven times per hour. The absence of the reflex in patients with faecal incontinence would indicate a weakness of the IAS, whereas in Hirschsprung's disease (segmental aganglionosis), it would be associated with obstructive defaecation rather than faecal incontinence. However, the value of this test is limited as the RAIR may be difficult to elicit consistently, even in healthy subjects.

The external anal sphincter

The EAS is inseparable from the puborectalis posteriorly, and both muscles appear to function as a single unit electrophysiologically. It has been shown that while contraction of the puborectalis accentuates the anorectal angle, it does not increase the intraluminal pressure of the anal canal.

The EAS, similar to the IAS, is in a state of tonic contraction, even at rest, and the activity is reflexly raised when intra-abdominal pressure is increased (e.g. when coughing, laughing or lifting). Activity is maximally raised when the EAS is contracted voluntarily, but contraction can only be maintained for 1–2 min. Stimulation of the perianal skin also results in a reflex EAS contraction via the pudendal nerve, called the 'cutaneo-anal reflex'. Electrical activity usually decreases during straining and when defaecation is attempted, although this is described as a variable response in some subjects.

The EAS contributes up to 30% of the resting pressure, and the increment of the squeeze pressure above the resting pressure predominantly reflects EAS function. The maintenance of tone is, however, also dependent on a sensory input, as it is lost if the sensory roots are destroyed (e.g. *tabes dorsalis*).

The response to changes in intra-abdominal pressure suggests that the EAS is actively involved in the preservation of continence. Further support for this hypothesis is that division of the internal sphincter alone can be associated with minor degrees of incontinence to flatus and liquid stool, but not usually to solid stool. These properties of the EAS may be diminished either by denervation, mechanical trauma or a combination of factors.

The anal cushions

The anal cushions, consisting of epithelium, subepithelium and the underlying haemorrhoidal plexuses, can contribute up to 15% of resting pressure. The anal sphincters cannot obliterate the lumen completely without the sealing effect of the anal cushions. The thickened cushions may account for the increased resting pressures seen in patients with haemorrhoids. The decrease in resting pressure following haemorrhoidectomy may explain the development of minor anal incontinence, although inadvertent damage to the

sphincter, particularly the internal sphincter, has been observed using anal endosonography.

Rectal compliance

A compliant rectal reservoir that can accommodate large volumes of stool without significant increases in pressure is an important prerequisite for the effective function of barrier mechanisms of continence. Patients who have a reduction in rectal capacity, as occurs in colitis and radiation proctitis, often suffer from faecal urgency and incontinence.

Anorectal sensation

The epithelium of the anal canal is richly supplied with sensory nerve endings, exquisitely sensitive to pain, heat and cold. The afferent nerve pathways for anal canal sensation is via the posterior inferior haemorrhoidal branches of the pudendal nerve and anterior haemorrhoidal branches of the perineal nerve to the sacral roots of S2, S3 and S4, but in addition, direct anal and urethral branches arise from S4 and S5. Sampling has been shown to occur less frequently in incontinent patients compared with controls.

Central control of anal continence

The upper motor neurones for the voluntary sphincter muscles lie close to those of the lower limb musculature in the parasagittal motor cortex. They communicate by a fast conducting oligosymptomatic pathway, with the Onuf nucleus situated in the sacral ventral grey matter, mainly S2 and S3. The frontal cortex is important for the conscious awareness of the need to defaecate and appropriate social behaviour. Disease affecting the upper neurone motor pathway usually results in urgency and urge incontinence, and provided the lower motor pathway is still intact, reflex defaecation will still be possible. Neurological diseases such as multiple sclerosis, Parkinson's disease and disorders of the spinal cord or cauda equina can be accompanied by incontinence because the central pathways which control sphincter function are located in the vicinity of the cortico-spinal tracts. Patients suffering with diabetes mellitus can have an autonomic neuropathy and this can also lead to faecal incontinence.

The lower motor neurones innervating the striated pelvic floor and urethral and anal sphincters arise from the Onuf nucleus. The most common cause of a lower motor neurone lesion in the adult is chronic stretching of the pudendal nerve, usually as a result of chronic straining at stool and/or childbirth. Damage to the pudendal nerve results in progressive denervation and reinnervation of the pelvic floor–anal sphincter complex, causing weakness and atrophy of these muscles.

Pathophysiology of anal incontinence

The development of anal incontinence may be due to either mechanical disruption or neuropathy, but sometimes both coexist. Obstetric trauma is a major cause of such injury, although the peak incidence appears to be in the perimenopausal years. The development of anal endosonography has revolutionized our understanding of anal incontinence, and it has now been demonstrated that approximately one-third

of primiparous women develop anal sphincter injury that is not recognized during vaginal delivery. However, even when it is recognized and repaired, the outcome is suboptimal as one-third continue to suffer impaired continence. Attention is now being focused on improved training in anatomy and repair techniques. However, there are other factors such as the effect of ageing, collagen weakness, progression of pelvic neuropathy, oestrogen deficiency, concurrent irritable bowel syndrome, primary degeneration of the IAS, severe constipation and uterovaginal/rectal prolapse that may contribute to a deterioration in anorectal function.

Effects of continence surgery on mechanisms of continence

The most common operation for faecal incontinence is an overlap anterior sphincteroplasty which serves to re-establish the continuity of the anal sphincter muscle ring in patients with a sphincter defect. In addition, some surgeons perform a levatoroplasty while others imbricate the internal sphincter. This operation has a success rate of 70–80%, although this can deteriorate to nearer 50% by 5 years. Anal pressures, particularly the voluntary squeeze pressure, increase. Pelvic neuropathy can cause atrophy of the sphincter muscles and hence have an adverse outcome. Some studies have suggested that a prolonged pudendal nerve latency prognosticates a poor outcome, but other studies have failed to identify a correlation. An abnormally prolonged latency of >2.4 ms in isolation correlates poorly with anal squeeze pressures, and therefore some neurophysiologists believe that this is not a good test of neuropathy as it is only a measure of conduction in the fastest conducting motor fibres of the pudendal nerve.

The postanal repair is performed when faecal incontinence is due to a neurogenic cause leading to pelvic floor atrophy. The intention is to recreate the anorectal angle by placating the levators at the back of the rectum. However, current evidence indicates that this operation does not have a significant effect on the anorectal angle, but appears to increase the functional length of the anal canal and may improve anal canal sensation.

Other surgical options include stimulated gracilis muscle neoplasty and artificial anal sphincter.

Table 50.2 Comparison of bladder and bowel conditions

Bladder	Bowel
Detrusor overactivity	Irritable bowel syndrome
Urodynamic stress incontinence	Faecal incontinence
Detrusor sphincter dyssynergia	Anismus
Urgency	Urgency
Hypotonic bladder	Constipation

Sacral nerve modulation is a relatively new technique that has added a new dimension to the management of faecal incontinence and defaecatory disorders. Short-term results are very encouraging with minimal morbidity. This technique provides new hope to women who otherwise would be left with no option but a stoma.

Comparison between Bladder and Bowel

Reflex adaptation of the rectum and bladder in response to filling are fairly analogous. There is an inverse relationship between distension and compliance. The 'irritable bladder' is more often found in patients with irritable bowel syndrome. The aetiology of faecal and urinary incontinence may also be comparable, and Table 50.2 compares bladder and bowel conditions.

Conclusion

An understanding of the mechanisms of urinary and anal continence is essential before one can discuss incontinence. Furthermore, if treatment is to be appropriately targeted, one must understand the anatomical deficiencies as repair of these often results in correction of function without causing new dysfunction. In the light of this type of knowledge, meaningful investigations can be carried out and treatment modalities selected on an individual basis.

KEY POINTS

1. The muscular, connective tissue and nerve components of the urethral and anal sphincter continence mechanisms are very similar. The levator ani and their contribution by means of the pubourethralis and puborectalis muscles play an important extrinsic striated muscle role for continence. Both mechanisms have smooth muscle components and a nerve supply largely from the pudendal nerves.
2. The bladder and urethra and the rectum and anal sphincter have complex autonomic innervation in addition to the somatic innervation that allows reflex interplay with the spinal cord and higher centres that provide proprioceptive information from either **bladder, bowel or rectum**. Closure of the urethra and the anal canal is vital in maintaining continence, and the ability to choose the time to relax these mechanisms is essential for normal control of both continence mechanisms.
3. Mechanical damage to both the fascia and muscles is thought to be the most important factor in the aetiology of both urinary and faecal incontinence, and anal sphincter defects have been shown to correlate with anal incontinence.
4. Successful repair for both urinary and faecal incontinence is aimed at restoring anatomy and function; imaging methods are useful in the identification of defects, which can subsequently be appropriately repaired.

URODYNAMIC INVESTIGATIONS	784	KEY POINTS	795

Introduction

Evaluation of lower urinary tract dysfunction

Symptoms of lower urinary tract dysfunction are common amongst women of all ages and are the cause of significant impairment of quality of life (QoL). The Leicestershire Medical Research Council study (Perry et al 2000) estimates that up to 26% of community-dwelling adults have clinically significant symptoms, and up to 2.4% have significant bothersome and socially disabling symptoms, which equates to more than 40 patients per general practitioner in the UK. A thorough assessment of the symptoms, their impact and the cause is key to their successful treatment. The current guidelines of the National Institute for Health and Clinical Excellence (NICE) suggest that the initial assessment must categorize incontinence based on symptoms, and that all patients should be assessed using a 3-day diary along with a urine dipstick (National Institute for Health and Clinical Excellence 2006). Initial treatment should be conservative, with urodynamics reserved for refractory or complicated symptoms.

The term 'urodynamics' refers to a variety of tests ranging from a simple flow rate to complex tests performed in specialized units. The role of tests is to determine the cause objectively and to quantify the severity of urinary symptoms.

Normal assessment prior to urodynamics includes clinical history in isolation or the additional use of structured questioning or standardized symptom questionnaires. The utility of an accurate history (primarily categorizing incontinence as stress, urge or mixed incontinence) has been confirmed as part of a health technology assessment in the UK (Martin et al 2006), and was subsequently endorsed by NICE (National Institute for Health and Clinical Excellence 2006). These guidelines also highlight the role of disease-specific QoL questionnaires which may allow assessment of bothersomeness of symptoms, and these are increasingly used for the assessment of patients with urinary tract dysfunction in both clinical practice and clinical trials. The International Continence Society's (ICS) standardization document of

2002 also states that subjective, objective and QoL end-points should be used as three separate measures of outcome (Abrams et al 2002). Ward and Hilton (2008) demonstrated that cure rates varied from 40% to 90% depending on the definition used, highlighting the importance of defining outcome measures accurately.

Urinary symptoms

The relationship between urinary symptoms, urodynamic investigations and QoL impairment is often complex. Weak correlations have been found between the presence of lower urinary tract symptoms and clinical measures such as urodynamics. Although urodynamic investigations determine the cause of urinary symptoms, they do not quantify their impact on women's QoL; therefore, all three components offer utility in the assessment of a patient.

Urinary symptoms may not consistently reflect the cause of lower urinary tract dysfunction, and hence there is a need for urodynamic investigations (Cundiff et al 1997). Jarvis et al (1980) compared the results of clinical and urodynamic diagnoses for 100 women referred for investigation of lower urinary tract disorders. There was agreement in 68% of cases of urodynamic stress incontinence, but only 51% of cases of overactive bladder. Although nearly all of the women with urodynamic stress incontinence complained of symptoms of stress incontinence, 46% also complained of urgency. Of the women with overactive bladder, 26% also had symptoms of stress incontinence.

Versi et al (1991), using an analysis of symptoms for the prediction of urodynamic stress incontinence in 252 patients, achieved a correct classification of 81% with a false-positive rate of 16%. Lagro-Jansson et al (1991) showed that symptoms of stress incontinence in the absence of symptoms of urge incontinence had a sensitivity of 78%, specificity of 84% and a positive predictive value of 87%. Where stress incontinence is the only symptom reported, urodynamic stress incontinence is likely to be present in over 90% of cases (Farrar et al 1975, Hastie and Moisey 1989). Even when women who only complain of stress incontinence and who have a normal frequency/volume chart are investigated,

65% have urodynamic stress incontinence and 8% have overactive bladder (James et al 1997).

The severity of urinary symptoms is often used as a measure of the impact of lower urinary tract dysfunction in both clinical practice and clinical trials. At its simplest, severity may reflect symptom frequency (e.g. the number of incontinent episodes, the number of daily voids or the number of episodes of nocturia). Measuring symptom frequency is relatively easy but offers little insight into their impact.

Quality-of-life assessment

Incontinence research requires that morbidity is measured by endpoints that assess different aspects and are not always independent, such as the number of micturitions and volume voided. The relationship of these endpoints to the lives of women is not well understood. For example, do fewer incontinent episodes or reduced volume of an incontinent episode improve QoL? There are probably individual factors involved which are centred around personal psychology, such as measures of hardiness or personal construct (Tooze-Hobson and Loane 2008). QoL measurement makes an attempt to standardize assessment of many aspects of these, including areas such as social, psychological, occupational, domestic, physical and sexual domains.

Wyman et al (1987) used the Incontinence Impact Questionnaire to show that women with overactive bladder experienced greater psychosocial dysfunction as a result of their urinary symptoms than women with urodynamic stress incontinence, although no relationship was found between the questionnaire score and the urinary diary or pad test results. Kobelt et al (1999) showed that the severity of symptoms of incontinence as expressed as frequency of voids and leakage correlates well with the patient's QoL and health status, as well as the amount that they are willing to pay for a given percentage reduction in their symptoms.

Symptoms may change over time as patients adapt. It is accepted that patients with stress incontinence may develop frequency in order to limit stress leakage, and that these symptoms may be more problematic than the stress urinary leakage itself. Irritative symptoms and voiding dysfunction can follow surgery for urodynamic stress incontinence, and voiding dysfunction and distressing antimuscarinic side-effects can follow drug treatment of overactive bladder. Such changes can have a negative impact on the overall QoL of patients.

The King's Health Questionnaire is a good example of a disease-specific QoL questionnaire which incorporates questions about both bothersomeness of symptoms and QoL (Kelleher et al 1997). It was specifically designed for the assessment of women with urinary symptoms, and has been shown to have good sensitivity to clinically relevant improvement in urinary symptoms in clinical practice and clinical trials (Kobelt et al 1999). In one study, the King's Health Questionnaire was used to assess the outcome of surgery (colposuspension) for the treatment of urodynamic stress incontinence. There was broad general agreement between objective urodynamic changes demonstrating continence as a result of surgery and symptom and QoL score improvements (Bidmead et al 2001). More recently, there have been attempts to integrate and standardize questionnaires with

the International Consultation on Incontinence Modular Questionnaire (<http://www.iciq.net/>, Avery et al 2004) and the Electronic Personal Assessment Questionnaire (www.epaq-online.co.uk), which have the advantage of being computer based and giving an instant result.

Urodynamic Investigations

QoL measures have been used to compare impact and also populations, but not to direct treatment. There is still a need to include a diagnosis in treatment options.

Midstream urine specimen

Urinary symptoms can be caused by a urinary tract infection and treatment may resolve symptoms. A significant bacteriuria is growth of 10^5 organisms/ml of urine and is usually associated with pyuria. The presence of epithelial cells, erythrocytes and casts is also noted. Urine can be screened for infection using Multistix strips which test for nitrites, blood and leukocytes. This has been shown to pick up 95% of urinary tract infections.

Urodynamic studies are associated with a 1% risk of urinary tract infection (Coptcoat et al 1988), based on the risk of catheterization, so there is no need for women to have routine prophylactic antibiotics. However, women with particular risk factors, such as diabetes, or voiding difficulties should be given prophylactic antibiotics.

Urinary diary

A urinary diary is a simple paper record of when and how much fluid a woman drinks and voids (Figure 51.1). The diary should be completed for a minimum of 3 days (National Institute for Health and Clinical Excellence 2006). Leakage episodes are recorded and (ideally) the precipitating event is also noted. The documented record is more accurate than memory alone, having reasonable test-retest reliability, particularly for incontinence episodes (Wyman et al 1991).

Figure 51.1 Diagrammatic representation of a urinary flow rate.

The functional capacity of the bladder is obtained and polydipsia, as a cause of polyuria, can be excluded. Unfortunately, the diary does not differentiate between the different urodynamic diagnoses (Larsson et al 1991, Larsson and Victor 1992). The urinary diary can also be used as a baseline for monitoring women undergoing bladder retraining. More recently, an electronic version has been launched commercially which ranks bladder capacity as a centile, matched for age and fluid intake (Amundsen et al 2007). This has the added advantage of an inbuilt character-recognition programme to combine the cheap cost of a paper diary with the rapid and accurate data manipulation of a computer system, and makes possible more quantitative clinical measures than are currently feasible.

Pad test

Pad tests differ according to the length of the test and the volume of fluid within the bladder. The ICS has defined a standard 1-h pad test with a 500 ml oral fluid load (Abrams et al 1988). This involves wearing a weighed towel and drinking 500 ml of water 15 min prior to starting the test. The woman performs 30 min of gentle exercise, such as walking and climbing stairs, followed by 15 min of more provocative exercise, including bending, standing and sitting, coughing, hand washing and running, if possible. The towel is then removed and reweighed. An increase in weight of more than 1 g is considered significant. Limitations of the 1-h pad test and an oral fluid load is that it is not reliable unless a fixed bladder volume is used (Lose et al 1988), with other authors suggesting that it has a poor predictive value (Constanti et al 2008). A 24-h pad test correlates well with symptoms of incontinence, has good reproducibility and is positive if the weight gain is over 4 g (Lose et al 1989, Martin et al 2006). The extended pad test is a more lengthy and objective measurement of leakage, and can be used to confirm or refute leakage in those women complaining of stress incontinence which has not been demonstrated on cystometry.

Uroflowmetry

Uroflowmetry is a simple non-invasive investigation and can be easily performed as an outpatient. Flow meters are relatively inexpensive and give a permanent graphic record.

Indications

Measurement of the flow rate is indicated in women with complaints of difficulty in voiding, neuropathy, a past history of urinary retention and prior to continence surgery. It is advisable for any incontinent woman to exclude voiding difficulties.

Measurements

The flow rate is defined as the volume of urine (in ml) expelled from the bladder each second. The flow time is the total duration of the void and includes interruptions in a non-continuous flow. The maximum flow rate is the maximum measured rate of flow, and the average flow is the volume voided divided by the flow time. The total

Figure 51.2 Gravimetric urinary flow meter.

volume voided can be calculated from the area under the flow curve. The two most useful parameters are the maximum flow rate and the voided volume, which should ideally be greater than 150 ml. However, the Liverpool nomograms (Haylen et al 1989) will allow assessment of flow rates at a lower volume. In women with intermittent flow, the same parameters can be used but time intervals between flow episodes must be discounted. Lower volumes at presentation are more likely in the elderly and those of lower parity with a diagnosis of sensory urgency or detrusor overactivity (Haylen et al 2009).

Equipment

There are three main types of flow meter. The gravimetric transducer measures the weight of urine voided over time and this is converted to a flow rate (Figure 51.2). The rotating disc flow meter has a disc spinning at a constant speed. The voided urine slows the rotating disc. The flow rate is calculated from the amount of power needed to maintain the disc spinning at a constant speed. The capacitance flow meter has a metal strip capacitor attached to a plastic dipstick inserted vertically into the jug containing the voided urine. The rate and volume changes are measured by a change in electrical conductance across the capacitor. This is the most expensive type of flow meter, but is robust and very reliable.

Abnormal flow rates

Nomograms for peak and average urine flow rates in women have been constructed from flow rates of 249 normal women (Haylen et al 1989). These allow comparison of a single value with a standard flow rate. A flow rate below 15 ml/s on more than one occasion is taken as abnormal when the voided volume is above 150 ml as flow rates on smaller volumes are less reliable.

Figure 51.3 Urinary flow rate showing a prolonged flow with a low maximum peak flow rate suggestive of a voiding disorder.

Figure 51.4 A high-pressure, low-flow pattern suggesting a voiding disorder.

A low peak flow rate and a prolonged voiding time suggest a voiding disorder (Figure 51.3). Straining can give abnormal pressure flow patterns (Figure 51.4) showing a high-pressure, low-flow pattern suggestive of obstruction. The cause of voiding dysfunction may be determined by measuring intravesical pressure simultaneously.

Cystometry

Cystometry involves measurement of the pressure/volume relationship of the bladder during filling and voiding, and is the most useful test of bladder function. It is a simple and accurate investigation, and is easy to perform.

Indications

Cystometry is indicated in patients with symptoms refractory to conservative or simple treatments, or patients with complex symptoms (National Institute for Health and Clinical Excellence 2006). However, the validity of the conclusions of NICE have been challenged and management without cystometry may be less accurate (Agur et al 2009).

Equipment

Twin-channel cystometry requires two transducers (external or microtip), a recorder and an amplifying unit (Figure 51.5). Bladder pressure is measured using a fluid-filled line attached to an external pressure transducer or a solid-state microtip pressure catheter. A rectal catheter is required to measure abdominal pressure; this is a fluid-filled, 2-mm-diameter catheter covered with a rubber finger cot to prevent blockage with faeces when the catheter is inserted into the rectum (Figure 51.6). The upper edge of the pubic symphysis is the zero reference for all measurements, which are made in centimetres of water (cmH₂O). External transducers are cheaper and less fragile, but the microtip transducer does not suffer from movement artefact.

The bladder is filled using a 12F catheter with a continuous infusion of normal saline at room temperature. The standard filling rate is between 10 and 100 ml/min and is provocative for overactive bladder. Slow-fill cystometry at a rate of 10–20 ml/min is indicated in women with neuropathic bladders. Rapid filling at over 100 ml/min is rarely used, but can be a further provocative test for overactive bladder. There is now an ICS standard for manufacturers to adhere to, and

most modern equipment will easily meet this standard. Choice of equipment must be on personal requirements.

Measurements

The parameters measured are the intravesical pressure (measured with the bladder transducer) and the intra-abdominal pressure (measured with the rectal line). The detrusor pressure is obtained by subtracting the abdominal pressure from the intravesical pressure, and is displayed simultaneously. The flow rate, filling and voided volumes are also displayed.

Method

Women attend having completed a bladder diary with a comfortably full bladder. The woman then voids on the flow

meter. The woman is then examined and the residual volume is noted on catheterization. During filling, the woman is asked to indicate her first desire to void and the maximal desire to void, and the volumes of these events are noted. There is evidence that women with overactivity may experience different sensations during filling compared with their stress-incontinent comparators (Digesu et al 2009). Systolic detrusor contractions and their association with urgency are noted. Precipitating factors, such as coughing or running water, are also noted. Any symptomatic detrusor pressure rise on standing is again recorded.

At the end of filling, the filling line is removed and the woman stands up. She is asked to cough and leakage is noted. Care must be taken to avoid artefact from the pressure lines moving. Provocative tests for overactive bladder, such as listening to running water and hand washing, are performed at this stage. The woman then transfers to the commode and voids with the pressure lines still in place.

Normal cystometry

The following are parameters of normal bladder function.

- Residual urine of less than 50 ml or 10% of voided volume.
- First desire to void between 150 and 200 ml.
- Capacity (taken as strong desire to void) of greater than 400 ml.
- Detrusor pressure rise on filling of less than 15 mmH₂O per 500 ml infused.
- Absence of systolic detrusor contractions.
- No leakage on coughing.
- No significant pain on filling.
- A detrusor pressure rise on voiding (maximum voiding pressure) of less than 50 cmH₂O, with a peak flow rate of more than 15 ml/s for a voided volume over 150 ml.

Abnormal cystometry

Urodynamic stress incontinence is defined by the ICS as leakage on coughing in the absence of a rise in detrusor pressure (Figure 51.7). It is therefore a diagnosis of

Figure 51.5 Urodynamic equipment showing the computerized cystometry unit.

Figure 51.6 Pressure lines for cystometry. Clear bladder filling line with blue bladder pressure and red rectal pressure lines.

Figure 51.7 Cystometric trace showing urodynamic stress incontinence. The detrusor line remains flat. Each arrow indicates a cough, when leakage occurred.

exclusion, as cystometry by itself cannot determine bladder neck or urethral function; radiographic imaging or the addition of urethral function tests is required. Urodynamic detrusor overactivity is diagnosed during the filling phase if spontaneous or provoked detrusor contractions occur while the woman is attempting to inhibit micturition (Figure 51.8). Low compliance is diagnosed when the pressure rise is more than 15 cmH₂O on filling the bladder with 500 ml of fluid and does not settle after filling is stopped. These parameters are all given in the ICS good practice document (www.icsoffice.org).

Laboratory urodynamics does not provide a diagnosis in 15–25% of symptomatic women. If a laboratory test fails to answer the framed question, the investigator may feel that there is a need to request a further test. A recent study has reaffirmed the importance of urodynamics in women with symptomatic prolapse where 33% had their management changed as a result of urodynamics, including 7% having their surgery changed (Jha et al 2008).

Ambulatory monitoring

Standard twin-channel cystometry is carried out in an artificial environment over a short time frame with a filling rate that is not physiological. The test also renders the woman immobile, and bladder abnormalities produced by

movement may be missed. Ambulatory urodynamic monitoring was introduced to avoid these problems, using portable digital data storage units attached to the woman for periods of several hours (van Waalwijk van Doorn et al 1991, Webb et al 1991, Anders et al 1997).

Technique

The woman wears her normal outdoor clothing and has a digital recording system (Figure 51.9). Intravesical and rectal pressures are recorded using microtip pressure transducers at a rate of 1 Hz. The ambulatory recording device can be used in conjunction with an electronic leakage detection system, and when the woman wishes to void, she connects the recorder to a flow meter and then voids. The test can last up to 6 h in clinical practice. The women are encouraged to mobilize and continue normal daily activities, including gentle exercise. Fluids should be encouraged and a minimum intake of 180 ml every 30 min is requested (Salvatore et al 1999). Antibiotic cover is not given as infection rates are less than 1%. At the end of the test, the woman is requested to attend with a full bladder and various provocative manoeuvres are carried out (similar to a standardized pad test). The woman will also keep a diary of events during the investigation, and the analysis occurs with the patient present referencing events recorded in the diary.

Figure 51.8 Cystometric trace showing detrusor overactivity. The arrows indicate where the woman complained of urgency and leakage occurred.

This investigation is available in specialist units and tends to be reserved for women in whom routine cystometry gives conflicting or unexpectedly negative results and where simple treatments have failed. This technique is more sensitive to the detection of abnormal overactive bladder in symptomatic women who had previously not been found to have an abnormality on laboratory urodynamics (Webb et al 1991, van Waalwijk van Doorn et al 1996). High rates of overactive bladder have been reported in asymptomatic controls (van Waalwijk et al 1992, Robertson et al 1994, Heslington and Hilton 1996). However, using a strict protocol for investigation and reporting, the high false-positive detection of overactive bladder in asymptomatic women is corrected (Salvatore et al 1996). There is some evidence that overactive bladder which develops after colposuspension may be occult and can be detected before surgery using ambulatory urodynamics (Khullar et al 1995). Ambulatory monitoring is time consuming and sometimes technically difficult. The equipment is expensive and fragile, which is important when women are being discharged home with the equipment *in situ*. Discomfort is a problem but is usually mild and more common in male than female patients. However, its utility has recently been reaffirmed (Pannek and Pieper 2008).

Radiology

General radiology

A plain abdominal X-ray is useful when symptoms suggest bladder calculi. Osteitis pubis is a rare complication of the Marshall–Marchetti–Krantz procedure, presenting with suprapubic pain, and is diagnosed on an anteroposterior pelvic X-ray. Sacral and lumbar spine X-rays are indicated if a congenital abnormality is suspected; for example, spina bifida and meningocele, which are important causes of neuropathic bladder disorders in children. Spinal cord trauma and tumours can also cause disturbances of micturition. Disc prolapse is common and is demonstrated on a myelogram.

Intravenous urography and computed tomography urogram

Intravenous urography is not indicated in most women with lower urinary tract symptoms unless for neuropathic bladder, suspected ureterovaginal fistula or haematuria. More commonly, a computed tomography urogram would be performed; whilst having a higher radiation dose, this also has a higher sensitivity for extrinsic pathology.

Figure 51.9 (A) Ambulatory recording box. (B) Microtip pressure transducers.

Videocystourethrography

Videocystourethrography (VCU) is radiological screening of the bladder synchronized with pressure studies of the bladder, recorded with a sound commentary on video (Figure 51.10). Stanton (1988) reviewed 200 cases of urinary incontinence following failed surgery, and concluded that VCU only had an advantage over cystometry in a few selected groups of women. VCU was indicated in women complaining of postmicturition dribble, which may be due to diverticulum (although magnetic resonance imaging is the gold standard for this diagnosis) (Figure 51.11).

Technique

The procedure is the same as for cystometry except the filling medium is Urografin 35% and the test is performed in a X-ray screening room. The main differences from cystometry are that the woman is tilted upright and positioned in the erect lateral oblique position. She is asked to cough and strain. Leakage, bladder neck opening and bladder base descent are all noted with X-ray screening. Any

Figure 51.10 Woman undergoing a videocystourethrogram.

Figure 51.11 Videocystourethrography showing a urethral diverticulum.

ureteric reflux and detrusor contractions are also noted. The woman commences voiding and is screened simultaneously; once the flow is established, she is asked to interrupt it. The ability of the urethra to milk contrast back into the bladder is noted.

All data are recorded and displayed at the same time as the bladder image. A sound commentary can also be recorded simultaneously.

Micturating cystogram

This investigation also involves radiological screening of the bladder but without pressure or flow measurements, and is therefore less useful in the investigation of incontinence. Its main value is to demonstrate vesicoureteric reflux, and abnormalities of bladder and urethral anatomy (e.g. diverticula, and bladder and urethral fistulae). It is not useful for the assessment of incontinence.

Ultrasound

Ultrasound is becoming more widely used in urogynaecology. Its most simple use is in the estimation of postmicturition residual urine volume and to assess the bladder neck and surrounding area.

Postmicturition urine estimation

This useful technique obviates the need for urethral catheterization with its risk of introducing infection. It is indicated in the investigation of women with voiding difficulties, either idiopathic or before surgery, and also following postoperative catheter removal. The bladder is scanned in two planes and three diameters are measured. As the bladder only approaches a spherical shape when it is full, a correction factor has to be applied. Several different formulae have been devised, and the most common is to multiply the product of three diameters (height \times width \times depth) by a figure of 0.625 (Hakenberg et al 1983). This has an error rate of 21%, which is acceptable. Ultrasound machines are expensive and not always available in the community setting, in clinics or on the postoperative ward where residual volumes often need to be measured. The bladder scan is a portable ultrasound device designed for the measurement of bladder volume (Figure 51.12). The machine calculates the urine volume using preconfigured settings without the operator needing to perform any mathematical calculations, and results are similar to those obtained with complex ultrasound technology for the assessment of residual urine assessment. These become inaccurate at higher volumes, but this is not of clinical significance as the relevance of a high residual, regardless of the amount, remains. The role of this technique is limited in the immediate postoperative period in a woman with an abdominal wound, and also post partum where lochia can lead to a false-positive result.

Bladder neck position

Ultrasound scanning of the bladder neck has been used as an alternative to radiological screening, and has been reported to give equivalent information to the clinician (Brown et al 1985, Richmond et al 1986).

Ultrasound of the bladder neck has been performed using the transabdominal (White et al 1980), rectal (Shapeero et al 1983), vaginal (Hol et al 1995) and transperineal (Khullar et al 1994a) routes. The transabdominal view of the

Figure 51.12 Portable ultrasound scanner used for detecting postvoid urinary residuals.

bladder neck is difficult in obese women, and there is no fixed reference point when assessing bladder neck movement. Transperineal measurement of bladder neck excursion with a specific Valsalva pressure in the antenatal period appears to predict the development of postnatal stress incontinence (King and Freeman 1998).

Vaginal, rectal and perineal probes use the lower border of the public symphysis as a fixed reference. The rectal probe is less acceptable to women, and difficulties arise with rotation of the probe, causing loss of the image.

Transvaginal ultrasound

The vaginal probe has been used successfully to image the bladder neck. Descent of the bladder base, together with bladder neck opening, has been demonstrated in a majority of women with stress incontinence but not in controls (Quinn 1990). However, bladder neck opening also occurs with overactive bladder, and this may be difficult to distinguish from stress incontinence unless there is a concomitant bladder pressure recording. The bladder neck can be compressed by the transvaginal ultrasound probe, preventing urinary leakage (Wise et al 1992). The potential for distortion of the bladder neck by the probe has not been fully assessed. Transvaginal ultrasonography has been used to measure bladder wall thickness (Khullar et al 1994b, 1996a) (Figure 51.13). Women with urodynamically diagnosed overactive bladder were found to have significantly thicker bladder walls than women with urodynamic stress incontinence, and this has been proposed as a screening and diagnostic test. However, the role of this has been challenged recently (Leksuichai and Dietz 2008).

Perineal ultrasound

Perineal scanning is the most readily available and least expensive technique. It is less likely to cause pelvic

Figure 51.13 Transvaginal ultrasound picture showing measurement of bladder wall thickness in a woman with a diagnosis of detrusor overactivity.

Figure 51.14 Transperineal two-dimensional ultrasound scan of the bladder neck.

distortion, is more acceptable to women and is feasible in obese women (Figure 51.14). The technique has been shown to be as accurate as lateral chain urethrocytography in the assessment of women with failed continence surgery. The equipment is accurate, portable and available in most gynaecology departments (Gordon et al 1989). It may be of use in the determination of causes of failed continence surgery (Creighton et al 1994).

Urethral ultrasound

Urethral cysts and diverticula can be examined using ultrasound. The disadvantage of this method is that unless the opening of the diverticulum is seen directly, the two cannot be differentiated. Intraurethral ultrasonography of the urethral sphincter has been described (Schaer et al 1998) and shows an association between decreased sphincter cross-sectional area and urodynamic stress incontinence. This is not used clinically at present.

Three-dimensional ultrasound of the urethra and urethral sphincter has been described (Khullar et al 1994c). This uses a perineal probe which records 150 ultrasound 'slices' as the probe scans 90° on its axis. A three-dimensional image is reconstructed, giving views of the urethra and rhabdosphincter (Figure 51.15). The volume of the urethral sphincter is larger in continent women compared with women diagnosed with urodynamic stress incontinence (Athanasίου et al 1995, Khullar et al 1996b). Evidence of damage to the rhabdosphincter is present in some women with severe urodynamic stress incontinence.

Investigations of urethral function

Urethral pressure measurement

Continence is maintained if the urethral pressure is higher than the intravesical pressure. Many methods of measuring urethral pressure have been used. It is usually measured with a catheter-tip dual-sensor microtransducer, although in the past, infusion catheters using fluid or gas and intraluminal balloons have been tried. The microtransducer system has two transducers which are 6 cm apart, 12 mm long and 1.6–2.3 mm in diameter, mounted on a 7F catheter. These catheters are easy to use but fragile and expensive.

Technique

The bladder is filled with 250 ml of physiological saline, and the catheter is passed so that both sensors are within the bladder. The catheter is then connected to a catheter withdrawal mechanism set at a standard speed of 5 cm/min and a chart recorder. The static urethral pressure is the urethral intraluminal pressure along its length with the bladder at rest. The dynamic urethral pressure (the urethral closure pressure) is the difference between the maximal urethral pressure and the intravesical pressure while the woman gives a series of coughs. Women with stress incontinence have a lower urethral closure pressure than continent women, and this is directly proportional to the severity of their incontinence (Hilton and Stanton 1983).

Clinical value

Urethral pressure measurements are useful in defining physical properties; however, their value in clinical practice is not certain, with some suggesting that this offers little added value in the prediction of outcome with contemporary sling surgery (Wadie and El-Hefnawy 2009). The static urethral pressure profile is useful to detect a low-pressure urethra where the urethral pressure is less than 20 cmH₂O, as these women have a 50% failure rate with conventional continence surgery. It has been suggested that they would benefit from a more obstructive procedure (Sand et al 1987).

The dynamic urethral pressure profile more closely approximates the clinical problem, but there is a large overlap for both the functional urethral length and the urethral closure pressure between normal and stress-incontinent women, and it is not possible to separate the two groups on urethral pressure profile alone. Versi (1990) compared the urethral

Figure 51.15 Three-dimensional scan of a rhabdosphincter.

pressure profile with VCU as the 'gold standard' investigation, and found that accurate diagnosis was not possible with the urethral pressure profile alone.

Urethral pressure measurements may be of value for the assessment of women following failed surgery and for the study of urethral diverticula or strictures.

Leak point pressure

Leak point pressures can be detrusor or abdominal. The detrusor leak point pressure is indicated in women who have incontinence and a neuropathic condition, or those who are unable to empty their bladders (McGuire and Brady 1979).

Abdominal leak point pressure is the pressure at which leakage occurs during either a cough or a Valsalva manoeuvre. The pressure can be measured using pressure catheters in the bladder, vagina or rectum. It has been proposed as a measure of urethral resistance of the urethral sphincter to increased intra-abdominal pressure (Robinson and Brocklehurst 1983). It is highly reproducible with a strong correlation with maximum urethral closure pressure. It is not clear whether this test is useful in the evaluation of urinary incontinence.

Cystourethroscopy

Cystoscopy allows the urethra and bladder to be visualized optically. It is indicated in a small group of women with incontinence, but is not a part of the routine investigation of incontinence as it gives little information about function.

Indications

- Reduced bladder capacity at cystometry.
- Recent (<6 months) history of irritative urinary symptoms (e.g. frequency and urgency).
- Suspected urethrovaginal or vesicovaginal fistula or other anatomical abnormality.
- Suspected foreign body (e.g. after mesh surgery).
- Suspicion of interstitial cystitis.
- Haematuria unrelated to urinary tract infection.
- Need to exclude neoplasm in the presence of persistent urinary infection.

Cystoscopy comprises part of the operative technique in continence operations, such as the tension-free vaginal tape (TVT) procedure, to ensure that the TVT introducer needle has not passed through the bladder or in assisting in the

Figure 51.16 Cystoscopy with petechial haemorrhage and a Hunner's ulcer.

placement of injectables such as GAX collagen (Bard) or Macroplastique (Uroplasty).

Technique

Cystoscopy is a sterile technique performed under general or local anaesthetic. If it is used to assess reduced bladder capacity during urodynamic studies, it must be performed under general anaesthetic. The urethra is difficult to examine in women, and this is best done by withdrawing the cystoscope and using a urethroscope sheath. Residual urine should be noted, although it is not always accurate if the woman has not voided recently.

Bladder capacity is the volume at which filling usually stops using a 1-l bag of fluid under gravity feed. Using a 30° or 70° cystoscope, the mucosa should be inspected for abnormalities, such as signs of infection or tumour. A note is made on the state of the bladder and urethral mucosa, and the presence of normally situated ureteric orifices. Interstitial cystitis may be suggested by the presence of splits which bleed on decompression and a reduced capacity (Figure 51.16). If diverticula are present, an attempt must be made to see inside to exclude carcinoma and calculi. Bladder calculi may be present, particularly in women with neurogenic bladder and/or indwelling catheters. Abnormal areas must be biopsied.

Most makes of cystoscope are similar and, as they are often not interchangeable, it is preferable to stick to one type. A standard set should include a cystoscope, urethroscope sheath, 0°, 30° and 70° telescopes, a catheterizing bridge and a fiberoptic light. A set of biopsy forceps is essential, as is a method for dilating the urethra, such as a set of Hegar dilators or an Otis urethrotome. Flexible cystoscopes are more suitable for cystoscopy under local anaesthetic. If flexible cystoscopy has proven suboptimal, a formal rigid cystoscopy should be performed.

Electrophysiological tests

Electromyography

Electromyography is the study of bioelectrical potentials generated by smooth and striated muscles, and can be used

to evaluate pelvic floor damage in women with urinary or faecal incontinence and prolapse. A motor unit comprises a motor nerve and the fibres it innervates. The electrical potential generated during a contraction is called the 'motor nerve unit action potential' and this can be measured using electromyography. If denervation occurs, the remaining nerves sprout collaterals to reinnervate the muscle fibres, thus increasing the dispersion of the motor unit so that more fibres of a particular unit will fire together at one time. This is seen on electromyography as an increase in the amplitude, duration and number of phases of the action potential. If reinnervation is present, polyphasic potentials are seen.

Partial denervation has been proposed as the mechanism by which childbirth contributes to the aetiology of stress incontinence. Allen et al (1990) performed transvaginal electromyography on primiparous women before and after delivery, and detected a highly significant increase in mean motor unit potential duration which was positively associated with birth weight and length of the second stage of labour. Smith et al (1989) studied anal sphincter fibre density in women with stress incontinence and/or prolapse, and found an increased fibre density in all groups compared with normal controls.

Electromyography can be performed using surface electrodes, such as anal or vaginal plugs, and ring electrodes mounted on a urethral catheter, or it can be performed using needle electrodes inserted into the external anal sphincter or periurethral muscles. Single-fibre needles give more selective recordings and allow measurement of motor unit fibre density. A single-fibre reading is more difficult to obtain than concentric needle signals as the sampling area of the needle is less (Kreiger et al 1988), but it can be improved using ultrasound (Fischer et al 2000).

Sacral reflexes

Sacral reflexes indicate the integrity of the sacral reflex arc by measuring the conduction time between a stimulus and an evoked muscle contraction. Electrical stimuli can be applied to the skin over the clitoris while recording from the pelvic floor muscle using an electromyography needle, a ring electrode on a Foley catheter or an anal plug electrode. This technique has been used in the investigation of neurogenic bladder disorders, although its usefulness in the detection of 'lower motor neurone' bladder disorders is not clear.

Conclusion

Urinary symptoms cause significant morbidity. Evaluation requires detailed symptom, QoL and urodynamic assessment. Whilst understanding the nature of urinary symptoms and their impact on patients' lives is important, determining their cause requires simple and sometimes complex urodynamic investigations. Only by fully understanding the cause of lower urinary tract pathology can we hope to improve our understanding of lower urinary tract dysfunction and provide appropriate treatment. Future developments may include non-invasive cystometry using techniques such as near-infrared spectrometry to detect contractions (Macnab and Stothers 2008).

KEY POINTS

1. Urinary infection must be excluded before any urodynamic investigation takes place.
2. Clinical history may not be a universally good predictor of urodynamic findings.
3. Peak urinary flow rate measurement is indicated in all women with voiding difficulty, particularly prior to continence surgery, which may aggravate this.
4. Stress incontinence diagnosed on cystometry is a diagnosis of exclusion; it is assessed by leakage in the absence of detrusor contractions.
5. Cough-induced detrusor overactivity may clinically mimic urodynamic stress incontinence.
6. Women undergoing repeat continence surgery should have urodynamic studies (VCU) performed.
7. Intravenous urography is not indicated in the routine investigation of incontinent women.
8. Ultrasound and magnetic resonance imaging are more widely used in assessment of the incontinent woman, with the advantage that radiological screening can be avoided.
9. Cystoscopy must be performed in the case of recurrent or persistent irritative urinary tract symptoms to exclude malignancy.
10. Partial denervation of the pelvic floor following childbirth contributes to the development of both incontinence and vaginal prolapse.
